## ACKNOWLEDGMENTS

Brenda Rogers assisted in compilation of data and figures and Marcus Duke assembled the manuscript. Thanks also to Bruce Barrett of the Alaska Department of Fish and Game for providing several reports and preliminary catch and escapement statistics.

This project was funded jointly by Peter Pan Seafoods (major contributor), Trident Seafoods, Icicle Seafoods, and Crusader (through Pacific Seafood Processors Association), the Aleutian East Borough, and Concerned Area M Fishermen.

## KEY WORDS

sockeye salmon, fisheries, distribution, timing, Bristol Bay, North Peninsula

## INTRODUCTION

The salmon fisheries on the north side of the Alaska Peninsula have been conducted annually since the early 1900s. Most of the sockeye salmon (Oncorhynchus nerka) are caught in the Northern District, which is along the migratory route of the much more abundant Bristol Bay stocks (Fig. 1). Early in the history of the North Peninsula sockeye fishery, there was controversy as some Bristol Bay fishermen claimed the majority of the catch was from Bristol Bay stocks, while the Peninsula fishermen maintained that they were fishing on local stocks (Murphy and Barrett 1994). Several early tagging experiments and studies of the migrations of Bristol Bay sockeye (Straty 1975, Eggers 1984, Isakson et al. 1986, Rogers 1987a) demonstrated that most Bristol Bay sockeye salmon migrate well offshore and are unlikely to enter the nearshore salmon fisheries on the North Peninsula. However, some very large catches in this past decade and some scale pattern analyses indicating a significant presence of Bristol Bay sockeye (Geiger 1989, Swanton and Murphy 1992) have renewed the controversy as to the origins of sockeye caught in the North Peninsula fishery.

The most reliable method to determine the origins of salmon in a fishery is by tagging experiments, but such experiments are expensive and are unlikely to be conducted along the North Peninsula in the near future. However, some other methods, in addition to scale pattern analysis, can be used to examine this question. In this report we examine the North Peninsula runs and fisheries to determine whether there are any recent changes that are atypical of other sockeye salmon stocks. Then the Bristol Bay sockeye migrations are described with emphasis on run timing and onshore-offshore distribution. These data are combined to estimate the vulnerability of Bristol Bay sockeye to the North Peninsula fisheries. Finally, the age compositions in the North Peninsula catches are compared with those from offshore samples and the Bristol Bay catches to determine if any similarity exists.

## METHODS

The description of the North Peninsula sockeye salmon runs and fisheries was based on reports by the Alaska Department of Fish and Game (ADF\&G). The historical catches were compared graphically with other selected sockeye salmon runs to western and central Alaska to determine if the North Peninsula catch curve was typical or atypical of other sockeye stocks. The recent North Peninsula runs and harvest rates (exploitation rate or proportion caught) were compared with Bristol Bay statistics by linear correlation. The North Peninsula fishery is on a mixture of local and perhaps non-local stocks, and it is difficult to construct brood tables for the individual rivers, which would be desirable to compare with other sockeye salmon rivers. Therefore, most comparisons were made between composite North Peninsula and Bristol Bay runs.

A description of the adult migration of Bristol Bay sockeye from the North Pacific into the Bristol Bay fishing districts was made in past years by combining information from several sources (Straty 1975, 1977; French et al. 1976; Shumacher and Moen 1983; Pace 1984; Rogers 1987a, b; Eggers 1984) as well as our studies in 1984-85 (Isakson et al. 1986). The present
description incorporates results from the 1987 tagging experiment by ADF\&G (Eggers et al. 1991 and Rogers 1990) and stock separation studies within Bristol Bay (Cross et al. 1989, Stratton and Cross 1990, Stratton et al. 1992).

Bristol Bay run timing past Port Moller was estimated annually (1987-94) by combining inshore run statistics collected by ADF\&G (e.g., Stratton 1991) with Port Moller test boat catches collected by the Fisheries Research Institute (FRI). The Port Moller statistics begin in 1968; however, FRI has conducted the program only since 1987 (Helton 1991, Rogers 1994). Fishing begins June 11 and ends about July 5-10, and all statistics were summarized by 5-day periods. The daily runs in each fishing district were estimated by adding the catch to the escapement, which was lagged back to the fishing district from the counting towers. The daily runs to the Naknek/ Kvichak, Egegik, and Nushagak districts were combined by setting the Egegik runs 1 day earlier and the Nushagak runs 1 d later than the Naknek/Kvichak run. Daily proportions were calculated and then the Togiak and Ugashik runs were added (Appendix Table 1). This combined cumulative daily run was then graphically compared with the cumulative daily index catches at Port Moller to determine the best travel time to reconstruct the run past Port Moller. Since the Port Moller sampling did not extend to the end of the Bristol Bay run, the estimated travel time was greatly influenced by the timing of the early part of the run. Adjustments were made for some years based on the difference between the mid-point in the inshore runs and the $50 \%$ date of the Port Moller catches through July 5.

The onshore-offshore distribution of the Bristol Bay run along the North Peninsula was estimated from the index catches at four stations spaced from 33 to 63 nautical miles (nm) out from Port Moller (about 13 to 43 nm out from the Alaska Peninsula coastline, point-to-point). An index catch is the number caught by 100 fathoms ( fm ) fished for 1 hour with a monofilament net of 5inch mesh. To expand the onshore-offshore distribution, index catches at stations 10 nm inshore and 10 nm offshore of the standard four stations were estimated from the closest stations. This provided annual estimates of the onshore-offshore distribution by 5 -day periods and $10-\mathrm{nm}$ intervals from 3 to 53 nm off the coastline. The North Peninsula fishing districts extend out 3 nm from the coastline. The estimates of the daily passage of Bristol Bay sockeye were then multiplied by the estimated proportion of the run that was within 3 nm of the coast to estimate the number of Bristol Bay sockeye potentially available to be caught in the North Peninsula fisheries (Appendix Table 2). The main assumption is that the onshore-offshore distribution in the remainder of the Northern District is the same as that estimated off Port Moller.

The ages of sockeye caught in the Port Moller test fishery were summarized by 5-day periods to correspond with the test-boat catches (Appendix Table 3). The annual age compositions of the sockeye caught in the North Peninsula fisheries were provided in ADF\&G reports by weekly periods for two subdistricts: Bear River, Harbor Point to Cape Seniavin; and Ilnik/Three Hills, Cape Seniavin to Strogonof Point (Fig. 2 and Appendix Table 4). Age compositions from the two subdistricts were averaged through July 11 by weighting the subdistrict compositions by the catch. Catches made within Nelson Lagoon were not included because these were very unlikely to contain Bristol Bay fish. The annual age compositions of the North Peninsula escapements were estimated by weighting the individual river age compositions by the number in the escapement (Appendix Table 5). Unfortunately, the statistics were not available by date (the largest run, Bear River
extends from early June to September), ages were frequently missing for the smaller runs (e.g., Sandy River), and no data were available for 1993-94. For the remaining years the age composition of the North Peninsula escapement was estimated from Ilnik River, Bear River, and Nelson lagoon ages. Age compositions for the annual Bristol Bay catches are available in annual ADF\&G reports (e.g., Stratton and Crawford 1992); however, I used statistics from annual run summaries provided by B. Cross (ADF\&G, Anchorage, Alaska, unpubl. data) to calculate the age compositions in the catches (Appendix Table 6).

## RESULTS

## North Peninsula Sockeye Fisheries

Most sockeye salmon caught in the North Peninsula are caught by drift gillnets and secondarily by set gillnets (mainly Nelson lagoon), but some areas are open to purse seine gear. The drift fleet is virtually the same fleet that fishes the South Peninsula June fishery (False Pass). Since this June fishery often does not end until late in the month, fishing effort on the north side is light until the last week of June. The largest concentration of sockeye on the North Peninsula is in the area of Port Moller (Nelson Lagoon and Bear River); however, most of the catch is made east of there, towards Bristol Bay. The early historical catches from the North Peninsula averaged just under 1 million sockeye with the highest annual catch at 2 million (Fig. 3). This was followed by a period of relatively low production, 1950-77, and then the recent period since 1978 when several annual catches have exceeded the highest catches made in the early history of the fishery. The large recent catches in the North peninsula fishery are not unique to that fishery; rather they have occurred in nearly all major sockeye fisheries in the Bering Sea and upper Gulf of Alaska. The recent increase in North Peninsula catches is in fact modest compared with the increases in catches from neighboring Ugashik and Egegik systems or in Cook Inlet. The changes in the North Peninsula catches are more in line with the Nushagak and Chignik stocks.

Estimates of the annual runs (catch plus escapement) to the North Peninsula are only available since 1962 (McCullough et al. 1994). The Bristol Bay and North Peninsula runs both increased in the late 1970s from relatively low runs during the early 1970s (Fig. 4). There is thus some correlation in runs between the locations ( $\mathrm{r}=.73, \mathrm{n}=31$ ); however, several years with large Bristol Bay runs (1960, ‘65, ‘70, '75) had average or below-average runs on the North Peninsula. There is no indication from these data that the North Peninsula catches are dependent on the abundance of Bristol Bay sockeye. The North Peninsula runs extend over a much longer period than the Bristol Bay runs, which typically end in the bay by July 20 . Bear River has an early and late run. The early Bear River run, as well as most of the other North Peninsula runs, tends to overlap the period when Bristol Bay sockeye are migrating past the North Peninsula, June 20-July 11. The timing of the North Peninsula sockeye runs was approximated by the weekly catch plus escapements (with no lag time for travel from the fishing district to the counting stations) for 4 recent years with very large runs (Fig. 5). Much of the North Peninsula run and catch takes place while the Bristol Bay sockeye migration is underway; however, the division of catch and escapement is in line with
similar large runs within Bristol Bay. Along with the recent large runs to the North Peninsula, there have been escapements in excess of management escapement goals (Table 1). The same thing has happened in Bristol Bay with the recent large runs (Rogers et al. 1994). In both areas, fishermen have not harvested all the fish available in excess of management escapement goals with these large runs. Management based on fixed escapement goals should have low harvest rates when runs are small and high harvest rates when runs are large. This has been the case for the North Peninsula runs, but less so for Bristol Bay (Fig. 6).

## BRISTOL BAY SOCKEYE MIGRATIONS

## General Routes from the Pacific

The return migration of adult sockeye salmon to Bristol Bay begins in May as the maturing fish are distributed across the North Pacific from the eastern Gulf of Alaska to the western Aleutian Islands (French et al. 1976). The majority of the sockeye migrate through the Aleutian Island passes and the Bering Sea, but those located in the eastern and central Gulf of Alaska move north concentrating along the south side of the Alaska Peninsula, and then west to Unimak Pass and into the Bering Sea (Fig. 7). The fish returning from the Gulf of Alaska represent about $25 \%$ of the Bristol Bay run and are the sockeye that are fished by the False Pass fisheries at South Unimak and the Shumagin Islands (Rogers 1987a). During 1957-78 when there was a large high seas fishery north and south of the western Aleutians, $10 \%$ of the runs were caught by this fishery while $2 \%$ of the runs were caught by the False Pass fisheries ( $40 \%$ were caught in Bristol Bay and $48 \%$ went to the escapement). During 1979-94, when the Bristol Bay runs commonly exceeded 40 million and the high seas catch was negligible, the False Pass catch accounted for $3 \%$ of the runs with $62 \%$ going to the inshore catch and $34 \%$ to the escapement.

The very abundant Bristol Bay sockeye are joined on their migration by North Peninsula sockeye, Bristol Bay chum salmon (O. keta), and perhaps Kuskokwim chum salmon as well (Eggers et al. 1991). The migration route into Bristol Bay along the north side of the Alaska Peninsula is offshore with the main body of sockeye concentrated 10 to 50 nm from the coastline (Fig. 8). The adults are actively feeding, at least as far in as the area off Port Moller (Helton 1991). Their growth in the spring of their return is partially density dependent and is also affected by spring temperatures (Rogers and Ruggerone 1993). There is also a strong tendency for the adults returning to peninsula rivers from Nelson Lagoon to Ugashik to swim past their river of origin, into inner Bristol Bay, and then back out.

Inshore of the adult migration the Bristol Bay smolts are migrating seaward along the coast. They put on very little growth in inner Bristol Bay where food is scarce, but they grow rapidly in the vicinity of Port Moller (Straty and Jaenicke 1980). There is a progression in the seaward migration of Bristol Bay smolts as they migrate into the Bering Sea (Rogers 1987b and 1988). Ugashik smolt lead the way, followed by Egegik, Naknek, Kvichak, and finally Nushagak smolt. Little is known about the migrations of North Peninsula smolt; however, smolts from the major systems in Bristol Bay are spread out in time (May-August) in contrast to the concentrated adult
migration, and there is no evidence that growth in the first summer at sea is density dependent. The north side of the Alaska Peninsula serves as a nursery ground for several other fishes in addition to juvenile salmon (Isakson et al. 1986).

The salmon migrations along the north side of the Alaska Peninsula can be explained partly on the basis of the hydrology in this area (Pace 1984). There is a major flow of water into the Bering Sea through Unimak Pass that tends to circulate into Bristol Bay within about 5 nm of the coastline. This coastal current carries water from the peninsula rivers into Bristol Bay in the vicinity of Egegik where the current flows across towards the Nushagak and then back out into the Bering Sea. Smolts migrate seaward against this current whereas adult salmon migrate offshore, and those returning to peninsula rivers are out of the reach of their home-stream waters until they are well into Bristol Bay. In addition to the fact that the best fishing on peninsula stocks is usually on the north or bay side of the river, there is now evidence for this migration route from tagging on the South Peninsula and scale pattern analyses within Bristol Bay. Tagging in the False Pass fisheries demonstrated no difference in run timing of Bristol Bay stocks through the June fisheries on the south side (Eggers et al. 1991, Rogers 1990). The Ugashik stocks, which from their location relative to the tagging should have been the first to arrive at their home waters, were instead the last of the stocks to arrive. Scale pattern analyses of eastside stocks demonstrated that Ugashik sockeye were the most likely to be caught in another district (Table 2). During 1987-94, about $29 \%$ of the Ugashik runs were caught on the inside. Note also that more Egegik sockeye were caught inside in the Naknek/Kvichak district than outside at Ugashik. These recent studies provide further evidence of an offshore-inside and nearshore-outside migration route for Alaska Peninsula stocks.

## Run Timing

The timing of the annual return of salmon to Bristol Bay is relatively precise, usually varying from year-to-year by only a few days. Compared with other salmon runs, Bristol Bay sockeye return over a very short period as the majority of the sockeye pass through the fishing districts in 2 weeks. The runs tend to begin earlier and end later when the runs are very large ( $>40$ million). In the large runs since 1987, there have been days when as many as 4 million sockeye swam past Port Moller (Fig. 9). The large runs in 1993 and 1994 ( $\sim 50$ million) illustrate the extremes in the daily passage rates. The 1993 run was one of the earliest runs on record and the 1994 run was one of the latest runs. For both runs the daily passage rate by Port Moller declined to $<500,000$ after July 10 and the runs were nearly over by July 15 . On the average the fish took 7 days to travel from Port Moller into the fishing districts with a range of plus or minus 2 days (Table 3). During the course of an annual run, water temperatures off Port Moller increase and there is a tendency for travel time to decrease (Rogers 1994). The early fish appear to take a day or two longer to reach the inner bay and the late arriving fish take a day of two less than the majority of fish in the middle of the migration.

## Onshore-Offshore Distribution

During the early period of the Port Moller program (1968-85), ADF\&G routinely fished at 11 stations spaced 5 nm apart along a transect out from Port Moller. Occasionally there was also fishing at station 0 ( 13 nm out from Port Moller) and station 12 ( 83 nm from Port Moller). The program was only moderately successful in forecasting the Bristol Bay run and was discontinued after 1985. These ADF\&G catch statistics were examined in 1987 before FRI took over the program. We decided to routinely fish only at stations $2,4,6$, and 8 because this is where large catches were consistently made; however, we would occasionally fish at stations 0 and 10 if the distribution was unusual (Table 4, Fig. 10). The present Port Moller program has been very successful in forecasting the abundance and timing of the Bristol Bay runs, and this is certainly due in large part to sampling the main body of sockeye salmon at stations 2-8 (Rogers et al. 1994).

## Vulnerability to North Peninsula Fisheries

Although large numbers of Bristol Bay sockeye annually migrate past the North Peninsula while an intensive commercial fishing is taking place (June 21-July 11), relatively few are vulnerable to this fishery because most Bristol Bay sockeye are far offshore (Table 5). On a daily basis, the largest number of Bristol bay sockeye estimated to have been vulnerable to the North Peninsula fishery was only 36,000 (June 25, 1987), and typically the numbers vulnerable were $<10,000$. The numbers of sockeye caught in the Bear River and Ilnik/Three Hills sections during open fishing periods were compared with the number of vulnerable Bristol Bay sockeye at those times. It was assumed that the Bristol Bay sockeye would have been harvested at the same high rates of North Peninsula stocks (.64-.81). During 1987-94, it was estimated that Bristol Bay sockeye contributed $\sim 3 \%$ to the total North Peninsula catch (annual range: $1-8 \%$ ) and the subsequent loss to the inshore Bristol Bay runs was $0.2 \%$ (annual range: $<0.1-0.3 \%$ ).

## AGE COMPOSITION

If Bristol Bay sockeye constituted a major portion of the North Peninsula catch as indicated by some scale pattern analyses (Geiger 1989, Swanton and Murphy 1992), then we should expect the age composition in the North Peninsula catch to be similar to that in Bristol Bay or at least an average of ages in Bristol Bay and the North Peninsula escapements. A comparison of age compositions can not be used to estimate the possible contribution of Bristol Bay sockeye, but it can rule out a majority contribution if the ages in Bristol Bay and North Peninsula are quite different.

Gillnets used in Bristol Bay tend to select for 3-ocean sockeye and against smaller 2-ocean fish and jacks. I assumed that the same held for gillnets used on the North Peninsula (i.e., greater proportion of 3-ocean fish in the catch than in the escapement) (Table 6). Therefore, to compare age compositions among fisheries and escapements, I used only the freshwater age compositions. This provided two observations for each location and year (the proportion of age 2.2 in ages $1.2+$ 2.2 ; and the proportion of age 2.3 in ages $1.3+2.3$ ). Freshwater age in Bristol Bay sockeye is influenced by spring and summer weather, which in turn affects growth and age of smoltification
(Rogers 1987c). We should thus expect some correlation in freshwater age composition between Bristol Bay and North Peninsula stocks because they are subject to similar weather.

There was a very high correlation in the freshwater ages of sockeye caught in the Port Moller test fishery and in the Bristol Bay catch (Fig. 11), which is further evidence that this test fishing is on a composite of all Bristol Bay stocks. The sockeye in the North Peninsula catches were (with one exception) older than the sockeye in the Port Moller and Bristol Bay catches but were comparable with the freshwater ages in the North Peninsula escapement. These age data are consistent with a North Peninsula fishery on North Peninsula stocks and with only a minor contribution from Bristol Bay stocks.

## DISCUSSION

The preponderance of evidence indicates that the North Peninsula sockeye fishery fishes local stocks. Recent increases in the catches are little different than those seen in other sockeye salmon fisheries, and harvest rates, as well as escapement levels, are consistent with other sockeye salmon fisheries in the region. The major routes followed by Bristol Bay sockeye on their return migration from the North Pacific takes them well off the North Peninsula shore and effectively keeps them from contributing larger numbers to the nearshore North Peninsula fishery. There is considerable evidence for an offshore migration into Bristol Bay and then an inshore migration back out of Bristol Bay for stocks bound for rivers along the north side of the Alaska Peninsula from Nelson Lagoon to Ugashik. It appears just as likely that North Peninsula stocks are caught in eastside Bristol Bay fishing districts as it is that Bristol Bay stocks are caught in North Peninsula fisheries. Even with Bristol Bay runs as large as 50 million, the contribution to the North Peninsula catch was small and the impact on the Bristol Bay run was negligible.

These results are inconsistent with the scale pattern analyses conducted in recent years. A problem with scale pattern analysis is that all fish in the unknown sample, in this case the North Peninsula catch, are classified into the assumed standard categories. There is no allowance for an "other" category (i.e., fish originating from stocks not included in the standards). It is thus very important that all stocks potentially contributing to the suspected mixed-stock fishery be included in the set of standards. This is a problem for the North Peninsula since all stocks are not routinely sampled. In addition, Geiger's (1989) analyses assumed that all fish were either from the North Peninsula or Ugashik, and Swanton and Murphy (1992) assumed all sockeye to be from either eastside Bristol Bay stocks or North Peninsula stocks. In both cases the assumptions were not in agreement with our understanding of the Bristol Bay adult migration along the Alaska Peninsula.

Future investigations of the sockeye salmon of the North Peninsula should examine the timing of North Peninsula runs by river, and especially separate the early and late Bear River runs. It would be helpful to reconstruct the runs in the North Peninsula fishing districts by combining daily catches and lagged daily escapements. The Port Moller data should be examined to determine if there is any difference in age composition between inshore and offshore stations. Perhaps Nushagak sockeye are further offshore than eastside stocks, just as chum are farther offshore than
sockeye. A major assumption in our conclusions is that the onshore-offshore distribution at Port Moller persists in towards Bristol Bay at least as far as Strogonof Point. There is no way to test this assumption other than by sampling the migration at that point. We also assumed that Bristol Bay sockeye migrated at a constant speed during the course of the run. The effect of this assumption could be examined by methods similar to those employed by Eggers (1984). If future scale pattern analysis is undertaken, Bristol Bay standards should include all major rivers, and standards for the North Peninsula should include at least the four largest rivers.
