Dr. Gabrielle Rocap

Oceanography

Abstract

In the sunlit ocean, heterotrophic and photosynthetic microbes are prey for earth's most abundant predators. Viruses are regulators of microbial communities, terminating phytoplankton blooms, altering biogeochemical cycles through cell lysis, and driving evolution through horizontal gene transfer. However, viral infection in the marine environment is unquantified. My research seeks understand infection in the ocean through a model marine host-virus system and through coupled studies of virus diversity and gene expression in the field. The model host were diatoms, which contribute to global biogeochemical cycles, form the base of coastal food webs, and account for approximately one fifth of global photosynthesis. The first chapter details the isolation and characterization of a novel virus that infects the toxigenic diatom *Pseudo-nitzschia multiseriis*. The virus had the largest genome of any single stranded DNA (ssDNA) virus isolated, with a gene complement atypical for ssDNA viruses. The virus had a broad host range, infecting hosts

from the distantly related centric and pennate diatom groups. The infection dynamics were host dependent, varying orders of magnitude in burst size from 220 to 9,300 viruses cell⁻¹ and between 12-60 hours in latent period. The second chapter assesses the interactions of numerous *Pseudo-nitzschia* hosts and natural viral communities by isolating 41 new *Pseudo-nitzschia* and challenging them with 20 environmental virus samples. *Pseudo-nitzschia* cultures were infected in 8% of the crosses. Viral infectivity intensified during the summer when the most permissive hosts were isolated, and viral communities were most infective of co-occurring hosts. Genotyping of the *Pseudo-nitzschia* cultures revealed subgroups of genetically identical hosts that were differentially infected suggesting that diatom diversity is an impediment to viral termination of diatom blooms. In the third chapter, viral infection was measured by comparing viral metagenomes to host metatranscriptomes on a coastal to open ocean transect. A small fraction of the total viral population was actively infecting. Viral groups such as the archeoviruses, virophage, and ssDNA viruses had different distributions and were differentially enriched in particle-associated and free-living metatranscriptomes. Viral expression was not correlated with virus to host ratios suggesting that microbial populations were at different stages of infection. Finally, auxiliary metabolic genes in *Synechococcus* phage were differentially expressed between stations despite similar community composition suggesting that auxiliary genes help viruses succeed under certain conditions. By linking culture based and culture-independent explorations of viral ecology, this research highlights the diversity of viruses in the ocean and the lifestyles that have made them successful.

Acknowledgements

There are truly not enough ways to thank all the people that have contributed to the work in this thesis and to the person who wrote it. Of course, none of this work would be written today without funding from the University of Washington, the National Science Foundation, the National Oceanic and Atmospheric Administration, and the Environmental Protection Agency. Unfortunately, clearly delineating the impact of individual people on this science or on myself is next to impossible. The people that I worked with in the Center for Environmental Genomics were unparalleled collaborators and friends. My committee believed in my abilities and encouraged my progress when I doubted the path before me. The undergraduates that worked with me, who are all far more talented than myself, provided the adventure, energy, and inspiration necessary to complete this research. I would not have been able to endure a Ph.D. without incredible friends, from those that were beside me daily to those that thought I studied coral cancer. I cannot be thankful enough of the unconditional support of my family who enabled me to pursue my dreams even from my earliest years. Finally, my adviser, Gabrielle Rocap, has undoubtedly shaped my life and my mind with wisdom, patience, and kindness.

Introduction

Viruses are earth's most and ancient and diverse predators (Nasir and Caetano-Anolles, 2015). They likely arose in the primordial ocean, multiple times, in tandem with the evolution of their cellular hosts (Koonin et al. 2006). They have kept signatures of their antiquity in their simple structures, a genome encapsidated in protein and sometimes lipids. Their genomes are comprised of single stranded or double stranded RNA or DNA (and sometimes a fusion of the two (Roux et al. 2013)) and span four orders of magnitude in size, from 1.7kb to 2.5 Mb (Finsterbusch and Mankertz 2009, Philippe et al 2013). Similarly, viruses themselves range in size from 17 to 600nm. No common gene unifies all viruses. However, viruses are all unified by their goal as parasites to replicate and produce more progeny viruses at the expense of their host. Viruses achieve this goal through many different types of lifestyles. Viral infection is a complex process where a virus binds to a host cell, migrates inside, and commandeers the host's metabolic machinery to replicate. Lysis concludes infection, releasing progeny viruses into the environment. Some viruses take detours from this path by integrating into their hosts' genomes (lysogeny), delaying their infection (latency), or infecting but budding off new viruses without killing the host (chronic infection). Together, these genomic, morphological, and functional characteristics shape the ecology of viruses and their hosts.

Life in the ocean presents substantial challenges for viruses. The ocean is patchy at many levels, driven by physical and chemical processes that profoundly influence marine microbial populations. At the global scale, temperature, light, and nutrients have created regimes that support different consortia of microbes (Longhurst et al. 1995, Follows and Dutkiewicz 2011). At the mesoscale, features can concentrate or disperse microbes by transporting water between biomes, such as from coastal regions to the open ocean in the case of eddies or from deep water

to surface water during upwelling (Monier et al., 2014). Zooming in even further, patchiness can be found even at the scale of a micrometer (Azam 1998, Stocker 2012). A single colony of the nitrogen fixing cyanobacterium *Trichodesmium* or a diatom seems like the city of Manhattan compared to viruses which would be ant sized (Finkel et al. 2009). In total, these processes create an ever-changing microbial landscape in a diffusive environment. For viruses in the ocean, finding a host may seem like a chance encounter, but viruses have been successful in this environment for billions of years.

The first marine virus was cultured in 1955 (Spencer, 1955), but only with the acknowledgement in 1989-1990 (Bergh *et al.*, 1989; Proctor and Furhman, 1990) of viruses being abundant, diverse, and ecologically relevant biotic entities in the ocean, did marine virology emerge as an integral discipline within oceanography. Viruses have since been identified as the most abundant predators on earth. In the ocean, where they number on average 10^7 per ml of seawater, viruses are thought to structure microbial communities as dominant contributors to cell death through lysis (Suttle 2007, Breitbart 2012). Also, viral lysis of hosts alters the global biogeochemical cycles mediated by microbes because of the release of cell contents into the water column. Finally, viruses are responsible for driving evolution through two mechanisms. First, evolution is influenced through predator-prey dynamics, in which hosts and viruses are constantly changing variable regions in their genomes to evade viral predation or attack new hosts (Stern and Sorek, 2011). Second, viruses transfer genetic material between organisms, allowing both viruses and hosts to explore new niches through new gene complements (Breitbart 2012). Therefore, viruses in the marine environment link microbial ecology, global biogeochemical cycles, and evolution.

Two contrasting methodological routes have sought to understand viral function and diversity: virus isolation and culture independent techniques, particularly metagenomics. The culturing of model host-virus systems such as *Vibrio* (Nakanishi *et al.*, 1966), *Prochlorococcus* (Sullivan *et al.*, 2003), *Synechococcus* (Waterbury and Valois, 1993), *Pelagibacter* (Zhao *et al.*, 2013), *Micromonas* (Cottrell and Suttle, 1991), *Phaeocystis* (Brussaard *et al.*, 2004), *Aureococcus* (Garry *et al.*, 1998) and *Emiliania huxleyi* (Schroeder *et al.*, 2002) have allowed detailed exploration of host-virus dynamics and demonstrated complex evolutionary patterns where hosts and viruses transfer genes to and from each other and fuel coevolution through the evolutionary arms race. These model host-virus systems have revealed strategies of how a virus infects and manipulates its host's physiology during infection (Lindell *et al.*, 2007; Vardi *et al.*, 2009). Recently, the genomic information from these systems has shed light on a sea of unknowns uncovered by metagenomics, a more recent and efficient method of capturing complex *in situ* dynamics (Angly *et al.*, 2006; Sharon *et al.*, 2009; Zhao *et al.*, 2013). Metagenomics has revealed equally interesting stories of viral diversity (Breitbart *et al.*, 2002), evolution (Alperovitch-Lavy *et al.*, 2011), and host dynamics (Rodriguez-Brito *et al.*, 2010) without the dependence on the culturability of both the host and the virus. However, most sequences in viral metagenomes are unable to be identified (Hurwitz and Sullivan, 2013). My research seeks to understand how viruses impact one of the most important groups of organisms in the ocean: diatoms.

Diatoms are the most abundant and genetically diverse group of marine eukaryotic phytoplankton (Armbrust, 2009). They contribute to approximately 20% of global photosynthesis (Field *et al.*, 1998) and are ubiquitously distributed in the marine environment. Because of this, diatoms are critical to global biogeochemical cycling (Nelson *et al.*, 1995). Their

silica cell walls or frustules cause them to be exported out of the euphotic zone upon death fueling the sequestration of carbon, silica, and other nutrients at depth, known as the biological pump (Smetacek, 2000). The success of diatoms in the oceans has been attributed to genomic plasticity allowing for diversification and the occupation of a wide range of niches (Bowler *et al.*, 2008). Diatom genomes are a mélange of genes that have come from a diversity of organisms including the ancestral heterotrophic eukaryote, photosynthetic endosymbiotic cyanobacteria, numerous non-phototrophic bacteria, and viruses (Armbrust *et al.*, 2004, Bowler *et al.*, 2008). Horizontal gene transfer, therefore, has played an essential role in the evolution of the diatoms. Finally, diatoms form the base of productive food webs as major primary producers. One genus of diatoms, *Pseudo-nitzschia*, is known for its ability to produce a neurotoxin, domoic acid, which can be biomagnified through food webs and can cause ecosystem disruptive effects and public health concerns (Bates *et al.*, 1989; Scholin *et al.*, 2000). These reasons make diatoms one of the most important microbes in the ocean. Furthermore, understanding the processes that structure diatom communities, influence diatom death, removal, and sinking, and shape diatom genomes is critical. Viruses play an important role in phytoplankton mortality, but understanding of the extent to which virus impact diatom biology is in its infancy.

The first diatom viruses were isolated and characterized a decade ago (Nagasaki *et al.*, 2004). Since then the number has grown to 15, and they have been isolated on 4 genera of diatoms, *Rhizosolenia*, *Chaetoceros*, *Thalassionema*, all centric diatoms, and *Asterionellopsis*, a pennate diatom (Nagasaki *et al.*, 2004, Shirai *et al.*, 2008, Tomaru *et al.*, 2009, Tomaru *et al.*, 2012, Nagasaki *et al.*, 2005, Bettarel *et al.*, 2005, Eissler *et al.*, 2009, Tomaru *et al.*, 2008, Tomaru *et al.*, 2011, Tomaru *et al.*, 2012, Tomaru *et al.*, 2013a, Tomaru *et al.*, 2013b, Kimura *et al.*, 2013, Toyoda *et al.*, 2012, Kimura and Tomaru, 2015). The diatom viruses have small

capsids typically less than 30 nm in diameter and burst sizes in the thousands of viruses per cell (Tomaru and Kimura 2015). They have narrow host ranges, often only infecting the original host (Tomaru and Kimura 2015). All diatom viruses have fallen into two groups based on their nucleic acid content of either single stranded RNA or single stranded DNA.

The genomes of the diatom viruses have been one of their most interesting characteristics. For the RNA viruses, all are positive sense ssRNA viruses that are closely related to other RNA viruses infecting protists (Tomaru *et al.*, 2013). In general, positive sense ssRNA viruses have small genomes, ranging from 4-26kb in length that frequently have poly(A) tails (Lang *et al.*, 2009). The hallmark characteristics of this class of viruses are their helicase gene, capsid protein, and RNA-dependent RNA polymerase (Rdrp), the main phylogenetic marker for this group of viruses (Lang *et al.*, 2009). RNA viruses that replicate using Rdrp are known for having near perilous mutation rates (Duffy *et al.*, 2008). During infection, for example, high rates of mutations result in quasispecies of progeny viruses, which helps the viruses survive in diverse environments (Duffy *et al.*, 2008). A handful of mutations found in the capsid gene of an ssRNA virus that infects the marine protist *Heterocapsa* were critical for determining the virus' host range and infectivity (Nakayama *et al.*, 2013). This highlights the importance of capturing sequence diversity in the ssRNA viruses as it can significantly affect virus-host infection dynamics.

The diatom DNA viruses with sequenced genomes form a new group of ssDNA viruses, the *Bacillariodnavirus* group (Toyoda *et al.*, 2012). The overarching characteristics of eukaryotic ssDNA viruses are genomes typically smaller than 6kb encoding less than 6 genes (Rosario *et al.*, 2012) including capsid genes, the replication initiator protein (Rep), and rolling circle replication protein (RCR) which have been commonly used to infer phylogenetic relatedness in

the eukaryotic ssDNA viral groups (Gibbs *et al.*, 2006; Koonin and Ilyina, 1992). Based on phylogenies of the Rep gene, the diatom viruses are distantly related to Circoviruses (Nagasaki *et al.*, 2005), which infect vertebrates, and Geminiviruses, which infect higher plants (Labonte and Suttle, 2013). While it may seem like ssDNA viruses have limited evolutionary space to explore due to small genome sizes and gene complement, ssDNA viruses are an incredibly diverse group at the sequence level. Their evolution is driven through two mechanisms. First, their rate of mutation can be on par with that of ssRNA viruses (Duffy *et al.*, 2008). This is reflected in ssDNA virus taxonomy, for example, with Anelloviruses that have within-genus genome nucleotide identity differences up to 80% (Rosario *et al.*, 2012). Second, ssDNA viruses are known for high frequencies of recombination leading to chimeric genomes (Lefeuvre *et al.*, 2009). This gene swapping is also an efficient mechanism facilitating the transfer of genes to host genomes. One example of a gene gained by recombination is a Rep protein from a nanovirus, which is a group of ssDNA viruses distinct from the diatom viruses, found in the nuclear genome of *Phaeodactylum tricornutum* (Liu *et al.*, 2011). The existence of the Nanovirus-like Rep gene in the genome of *Phaeodactylum* suggests that there may be other groups of ssDNA viruses besides the Bacillariodnaviruses that can infect diatoms, but have yet to be isolated.

Culture-dependent techniques have yielded a first and important glimpse at diatom virus diversity (Kimura and Tomaru, 2015). On the other hand, a handful of diatom virus-like genomes or genes have been assembled from metagenomes from viral communities (Culley *et al.*, 2006; Culley *et al.*, 2014, McDaniel *et al.*, 2014). Labonte *et al.* (2013) used methods to specifically target ssDNA viruses in the environment and were able to assemble over 590 new ssDNA viral genomes. However, none of these genomes were closely related to the known

diatom virus genomes. This highlights the need for more reference genomes of diatom viruses for phylogenetic comparisons. The scarcity of sequenced diatom viruses impedes insight into diatom-virus diversity and dynamics in the field.

Little is known about diatom-infecting viruses' influence on host community composition. Only one study has surveyed the abundance of known-diatom infecting viruses (Tomaru *et al.*, 2011a). However, viruses have been shown to affect host physiology and community abundance of several other harmful algal species. At the end of one mesocosm study in which the coccolithophorid *E. huxleyi* bloomed, virus-like particle abundance increased dramatically and viruses known to infect *E. huxleyi* also increased in abundance (Schroeder *et al.*, 2003). Glycosphingolipids, used as biomarkers of viral infection, also coincided with decreased *E. huxleyi* abundance in a transect through a coccolithophore dominated bloom (Vardi *et al.*, 2009). Finally, tracking a bloom of *Aureococcus* showed that the number of VLPs increased over the bloom and water from the bloom was able to lyse cultured *Aureococcus* (Gastrich *et al.*, 2004).

This thesis seeks to understand the diversity and function of viruses in the marine environment, focusing on viruses that infect diatoms. The approach in these three chapters bridges the gap that lies between culture based and culture-independent methods of environmental virology. Chapter one details the isolation and characterization of a novel diatom virus with a unique ssDNA genome and a broad host range. It lays the groundwork for a model diatom-virus system and expands the boundaries of viral genomic diversity. Chapter two looks to the field to understand the patterns of interactions between diatoms and their viruses. It explores temporal and spatial scales of infection as well as host permissivity to infection using diatoms of the genus *Pseudo-nitzschia*. Finally, chapter three assesses active viral infection in the ocean by

integrating viral metagenomes with cellular metatranscriptomes. Together they depict the varied lifestyles of viruses and how viruses control microbial communities in the ocean.

Chapter 1

A giant single stranded DNA virus with an origin in double stranded DNA phage

1.1 Abstract

Single stranded DNA viruses are some of the most successful yet simple pathogens on the planet, found in every environment and infecting organisms from all three domains of life. One of the ocean's most diverse and abundant primary producers, diatoms, are one of the few known hosts for ssDNA viruses in the ocean. A ssDNA virus was isolated and characterized using the diatoms *Pseudo-nitzschia multiseriis* and *Thalassiosira pseudonana*. The *P. multiseriis* DNA virus (PmDNAV) has two linear genome segments, 9,682 and 28,403 nt in length, the largest genome of any ssDNA virus. It also has an unusual gene complement for ssDNA viruses including a DNA polymerase B indicating novel replication dynamics for an ssDNA virus. The virus had no homology to previously sequenced ssDNA viruses and instead was more closely related to double stranded DNA viruses and prophage that are integrated into bacterial genomes. The virus indicates that a new type of ssDNA viruses originated from dsDNA viruses. These characteristics suggest that the PmDNAV has a unique lifestyle for ssDNA viruses and represents a new lineage of ssDNA viruses.

Viruses, earth's most ancient predators, likely arose in the primordial ocean multiple times, in tandem with the evolution of their cellular hosts (Koonin et al. 2006, Nasir and Caetano-Anolles, 2015). Single stranded DNA (ssDNA) viruses infect all three domains of life and are prevalent in nearly every environment sampled. They typically have genomes smaller than 10kb, which can be segmented (Rosario et al. 2009) and replicate via a distinctive rolling

circle replication (RCR) mechanism using proteins that are unlike the DNA polymerases found in cellular life and other double stranded DNA (dsDNA) viruses (Gibbs et al., 2006; Koonin and Ilyina, 1992). High mutation rates of their replication proteins (Duffy et al. 2008) and frequent recombination (Lefeuvre et al., 2009) drive the evolution of ssDNA viruses. These viruses have polyphyletic origins (Krupovic, 2013). Bacteria-infecting ssDNA viruses are thought to predate dsDNA viruses (Nasir and Caetano-Anolles, 2015), while eukaryote-infecting ssDNA viruses originated from the recombination of various bacterial plasmids with ssRNA viruses multiple times (Koonin et al. 2015). The eukaryotic marine phytoplankton group diatoms are one of the few known hosts for ssDNA viruses in the ocean (Nagasaki and Bratbak 2010), which is the largest reservoir of viruses on the planet (Suttle 2005). Here we detail the characteristics of a new diatom-infecting virus.

During a toxic bloom of the pennate diatom *Pseudo-nitzschia* at Sunset Beach, Oregon, USA in August 2009, the viral fraction (<0.2 μm) of water was infectious to cultures of *Pseudo-nitzschia multiseriis* CLnn-16. The virus was purified with a plaque assay and three dilution-to-extinction experiments. When treated with heat, UV, or filtered through a 0.02 μm membrane, the infectious potential of the lysates was eliminated. Viral particles with an icosahedral head that measured 50 nm (s.d. \pm 1.8 nm, n=10) in diameter and lacked a tail or an outer membrane were observed in electron micrographs of *P. multiseriis* CLnn-16 culture lysates using negative staining (figure 1a). In addition to infecting *P. multiseriis*, the virus also infected the centric diatom *Thalassiosira pseudonana* CCMP1335.

Viral nucleic acids were extracted from lysates of both *P. multiseriis* CLnn-16 and *T. pseudonana* CCMP1335. At least three fold more ssDNA than dsDNA was detected from viral nucleic acid extracts, and no RNA was detected (figure 1b). Digestion of viral nucleic acids with

DNase I (cleaves dsDNA and ssDNA) yielded signals below detection limits for both dsDNA ($<0.5 \text{ ng ml}^{-1}$) and ssDNA ($<1 \text{ ng ml}^{-1}$) (figure 1b). Digestion with S1 nuclease (cleaves ssDNA and ssRNA) also resulted in undetectable signal (figure 1b). Furthermore, when viral nucleic acids were sheared and ligated into plasmids, no *E. coli* colonies had viral inserts (n=48). Together, these data confirmed that the virus is a single stranded DNA virus, and it was named accordingly as *Pseudo-nitzschia multiseri*s DNA virus (PmDNAV).

The viral genome was assembled from two sources: ssDNA extracted and converted to dsDNA from lysates of *P. multiseri*s GGB1 and of *T. pseudonana* CCMP1335. The *T. pseudonana* DNA was sequenced with PacBio technology and the *P. multiseri*s DNA was sequenced with Sanger sequencing of paired-end clone libraries. Assembly of the Pac Bio reads resulted in 3 contigs, each with an average coverage of 3000x. The Sanger reads were 99.8% identical to Pac Bio sequence and, when mapped to the Pac Bio assembly, linked two contigs to generate two linear genome segments of 28,403 and 9,682 nucleotides (nt) in length (figure 2a). Both segments had 54% GC content. Terminal inverted repeats at both ends of the larger genome segment indicated the segment was closed. The second smaller segment had one terminal repeat. No mate pairs extended off the end of either segment. In total, 24% of the DNA is double stranded because of the terminal repeats, accounting for the signal detected using a dsDNA fluorescing dye (figure 1b). The PmDNAV has the largest genome, a combined 38,085 nt, of any known ssDNA virus. The larger genome segment alone is ~4,000 bases longer than the next longest ssDNA virus, the *Aeropyrum* coil-shaped virus (Mochizuki et al., 2012), and ~4x larger than the typical <10kb genomes of the majority of ssDNA viruses (Rosario et al. 2009).

To determine whether the two segments represented two separate viral genomes, several attempts were made to separate them. First, both genome segments were detected using segment-

specific quantitative polymerase chain reaction at every endpoint in 15 independent dilution to extinction experiments using axenic *T. pseudonana* CCMP1335. The probability that both genomes were detected at every end point if they were independent was $p < 0.05$ (supplemental table 1). Second, both segments purified between 1.35 and 1.4 g ml⁻¹ in cesium chloride density dependent gradients and thus were unable to be separated based on their densities (supplemental figure 1). Third, both segments increased approximately 5x in copy number simultaneously with the appearance of virus-like particles at 32 and 60 hours post infection in one step growth curves performed on axenic *P. multiseriis* PC9 and *T. pseudonana* CCMP 1335, respectively (supplemental figure 2). Thus, our interpretation of these data is that the two genome segments are contained in one virus.

The genome had 59 putative open reading frames (ORFs), of which 35 were similar to previously sequenced organisms and 12 had predicted functions (figure 2b, supplemental table 2). No genes were found that are common to previously sequenced ssDNA viruses such as the hallmark RCR endonucleases or capsid genes (Koonin et al. 2015). Genes involved in replication, specifically, a replication initiator gene, a transcriptional regulator gene, a helicase, and DNA polymerase B (polB), were located on the larger genome segment (figure 2b). Also, an HNH-endonuclease, which cleaves DNA at specific sequence patterns, suggested that the virus has the potential for horizontal gene transfer and genome rearrangement. Genes encoding viral structural proteins and maturation were located on the smaller genome segment (figure 2b). While the majority of ssDNA viruses have capsid genes with a double jelly roll fold (Abrescia et al., 2012), the PmDNAV capsid genes are predicted belong to a different structural lineage as they have HK97 fold domains (Pietila et al. 2011). A peptidase gene next to the capsid gene may be involved in the cleavage and maturation of the capsid genes to form the virion, and a gene

with an acetyltransferase domain may further modify viral proteins. Together, the replication and structural genes encoded on the separate genome segments complement each other by performing the functions necessary for viral infection, replication, and assembly.

The presence of these genes and particularly a polB is rare for ssDNA viruses. Only one other ssDNA virus, the *Bombyx mori* densovirus, encodes a protein-primed polB, which it may have acquired from the recombination between a parvovirus (ssDNA) and a dsDNA virus derived transposon (Krupovic and Koonin, 2014). It is likely the polymerase on the PmDNAV is DNA primed, and uses the inverted terminal repeats similar to the linear ssDNA parvoviruses to begin replication (Cotmorel, 1996). One of the major differences between ssDNA and dsDNA virus polymerases is that DNA polymerase B is, on average, less error prone than the RCR endonucleases of ssDNA viruses (Banach-Orlwsa et al. 2005). The rolling circle strategy is hypothesized to impose a genome size threshold on ssDNA viruses because of the rate of accumulation of deleterious mutations (Duffy et al. 2008), thus the genome size of the PmDNAV may not be constrained by errors during replication with a polB. In total, based on the content of both replication and structural genes, the PmDNAV appears functionally distinct from all other ssDNA viruses.

The functional differences between the PmDNAV and other ssDNA viruses likely lead to different ecological strategies. The other diatom-infecting ssDNA viruses have narrow host ranges, often infecting only the original host used for isolation, burst sizes up to 22,000 viruses cell⁻¹, and encode potentially highly error-prone RCR endonucleases (Kimura and Tomaru, 2015). Mutations may help alter the host range of ssDNA viruses (Duffy et al., 2008), and thus, with high burst sizes, may be a strategy to acquire new hosts and propagate in the water. The PmDNAV, on the other hand, produced 270 and 200 viruses cell⁻¹ upon lysis of axenic *P.*

multiseriis PC9 and *T. pseudonana* CCMP 1335, respectively (supplemental figure 2), and replicates with the less error prone polB. It also has a broad host range, able to infect both pennate (*Pseudo-nitzschia*) and centric diatoms such as *Thalassiosira*, *Ditylum*, *Skeletonema*, *Chaetoceros*, *Odontella*, and *Corethron* (supplemental table 3). Ultimately, this strategy is different than the other diatom infecting viruses; driven by different mechanisms that allow viruses to find new hosts, which might be rooted in their different polymerases and thus mutation rates.

The PmDNAV is phylogenetically unlike all other previously sequenced ssDNA viruses. The viral genome had no homology to previously sequenced ssDNA viruses based on blast with an e-value of $1e^{-2}$ (supplemental table 2). Genes that did have homology to previously sequenced organisms were either similar to bacteria which are likely putative prophage (28 genes) or dsDNA viruses (7 genes). Five of the 7 genes related to dsDNA viruses clustered together on the larger genome segment and were all involved in replication. Phylogenies indicated that two of these, polB and a helicase, were most closely related to Rhizobium phage (figure 2c). Rhizobium phage, which infect bacteria that are endosymbiotic with plants, are capable of horizontal gene transfer (Finan et al. 1984) suggesting, in addition to the endonuclease, that the PmDNAV may also share this capability. Genes outside this genomic island such as one of the capsid genes on the smaller genome segment and the replication initiator gene were more closely related to genes in bacteria, probably endogenous viruses, not to Rhizobium phage as seen with polB and the helicase genes (figure 2c). The differing evolutionary lineages and distinctive clustering of the genes on the PmDNAV indicate that the virus may have resulted from a recombination of two dsDNA viruses: an endogenous virus and a virus similar to Rhizobium phage. However, since the PmDNAV has an ssDNA genome, it is evidence that, at one point, a double stranded DNA

virus converted into a single stranded DNA virus.

The genomic characteristics and provenance of the PmDNAV do not fit within the current framework of the evolution of eukaryotic ssDNA viruses from the integration of ssRNA viruses with plasmids or within the hypothesis that bacteria infecting ssDNA viruses are an ancient group of viruses predating dsDNA viruses (Koonin et al. 2015, Nasir and Caetano-Anolles, 2015). Thus the PmDNAV likely represents a new lineage of ssDNA viruses and illuminates a novel pathway that has led to a group of ssDNA viruses that appears to have arisen from dsDNA viral elements. Ultimately, the PmDNAV may not just represent a new group of viruses, but suggests that the conversion from a single stranded to double stranded genome may be a more widespread phenomenon. Other viral ssDNA viral groups arising from dsDNA viruses may be populating the environment that have yet to be discovered.

1.4 Figure Legends

Figure 1.1 The morphology and nucleic acid content of the *Pseudo-nitzschia multiseriis* DNA virus. a) 2 virus particles of the *Pseudo-nitzschia multiseriis* DNA virus from a CLnn-16 lysate negatively stained and visualized with transmission electron microscopy. Scale bars are 100nm. b) Quantification of viral nucleic acids using Quant-iT high sensitivity DNA assays (blue), ssDNA assays (green), and RNA assays (orange) undigested and after digestion with DNAase 1 (cleaves dsDNA and ssDNA) and S1 nuclease (cleaves ssDNA and ssRNA). Colored lines denote the source of the nucleic acids, either extraction from lysates of *T. pseudonana* CCMP 1335 (red) or *P. multiseriis* CLnn-16 (cyan). Error bars represent the standard deviation of triplicate treatments. Boxes below the dashed line represent values that were below the limit of detection for the assay.

Figure 1.2 The genomic characteristics of the *Pseudo-nitzschia multiseriis* DNA virus. a) A schematic of the architecture of the two single stranded linear genome segments showing the inverted terminal repeats. b) The genome of the PmDNAV. Dashed lines indicate inverted terminal repeats. Open reading frames (ORFs) are indicated by arrows. ORFs are colored by their similarity to previously sequenced organisms: white denotes ORFs with no significant similarity to previously sequenced organisms, red denotes ORFs similar to double stranded viruses, and blue denotes ORFs similar to bacteria, likely prophage. ORFs with putative functions are labeled while ORFs without functions are not. Maximum likelihood phylogenies of genes representing the two different sources of genetic material in the PmDNAV genome c) DNA polymerase B (on the large genome segment representing dsDNA viruses) and d) a capsid gene (on the small genome segment representing bacteria/prophage). The PmDNAV is labeled in purple, bacterial sequences in blue, dsDNA viruses in red, and ssDNA viruses in green. Statistical significance of the branching pattern is passed on 100 bootstrap replications of the original alignment. Scale bars indicate genetic distance.

1.5 Supplemental figure legends

Supplemental figure 1. Genome segment quantification in density fractions from cesium chloride gradients. Bars represent the abundance of genome segment 1 (a) or genome segment 2 (b) in each fraction from either 1.2, 1.3, 1.4, 1.5, and 1.7 g ml⁻¹ or 1.25, 1.35, 1.45, 1.55, 1.7 g ml⁻¹ gradients.

Supplemental figure 2. One step growth curves of axenic *P. multiseriis* PC9 (a,c), and axenic *T. pseudonana* CCMP1335(b,d) infected with the *Pseudo-nitzschia multiseriis* DNA virus. Solid

lines represent control cultures while dashed line represent virus infected cultures. Closed squares indicate host abundance. Open circles indicate viruses per cell. Abundance in figures a-c is based on epifluorescent microscope counts. Genome copies (c,d) were determined with qPCR.

Supplemental figure 3. Maximum likelihood phylogenetic trees of the (a) replication initiator protein and (b) helicase. The PmDNAV is labeled in purple, bacterial sequences in blue, dsDNA viruses in red, and ssDNA viruses in green.

+ Lysed

- Resistant

*Virus:host ratios were determined by microscope based counts of the virus inoculum and the phytoplankton culture. Infectious units per cell vary from counted virus:cell ratios. For example, 1 infectious unit per cell for CLnn-16 and PC9 are 8 and 32 respectively.

1.7 Supplemental methods

Algal culture conditions

All cultures were maintained in f/2 medium + silica (Guillard and Ryther, 1962; Guillard, 1975) at 13 °C at an irradiance of 26 $\mu\text{mol photons m}^{-2} \text{s}^{-1}$ with cool white fluorescent illumination on a 16:8 light-dark cycle. Growth was monitored daily via chlorophyll-*a* fluorescence with a Turner 10-AU Fluorometer in glass test tubes or on a Spectra MAX m2 plate reader (Molecular Devices) in 48 well microtiter plates (Corning Inc. Costar).

Virus isolation

Surface seawater, 50L, was collected during a *Pseudo-nitzschia* bloom from Sunset Beach, Oregon (46°05'53N, 123°56'43W) on August 1, 2009. The water was pre-filtered through a 0.8 μm (Millipore) filter and concentrated to ~1L using a 30 kDa pore size tangential flow filtration system (Millipore). The concentrated sample was filtered through a 0.2 μm filter (Millipore) and the filtrate stored at 4 °C.

Cultures of *P. multiseriis* CLnn-16, 25ml, were inoculated with 7 ml of concentrated environmental sample and monitored via chlorophyll-*a* fluorescence. Control cultures were inoculated with 7 ml of medium. Four days post-inoculation, 12 ml of the culture volume was filtered onto a 0.2 μm (Millipore) filter. The filter was then stamped onto 1% (wt/vol) low melting point agarose (Invitrogen) in f/2 medium plates to create lawns of *Pseudo-nitzschia*. The plates were incubated as described above temperature and light conditions and monitored for plaque formation. Plugs of agarose containing plaques were inoculated into exponentially growing *P. multiseriis* CLnn-16. These cultures were monitored via chlorophyll-*a* fluorescence relative to a control, which was an agarose plug that contained healthily growing culture. To

ensure the virus was clonal, it was passaged through three dilution to extinctions (Suttle, 1993). Exponentially growing *P. multiseriis* CLnn-16 was inoculated with viral lysate in replicates of 5 over 8 10-fold dilution series in 48 well plates. Wells in which culture death was observed and had the most dilute virus concentrations were 0.2 μm filtered and used to inoculate the next round of dilution to extinction experiments. The virus was defined as clonal after three rounds of dilution to extinction. A one liter volume of exponentially growing *P. multiseriis* CLnn-16 was inoculated with the virus, lysed, 0.2 μm filtered and stored at 4 °C as a working stock for all later experiments.

Virus morphology

Virus samples were concentrated for electron microscopy with polyethylene glycol (PEG) precipitation. One liter of late exponential phase *Pseudo-nitzschia* CLnn-16 was infected with 30 ml viral working stock and cells were harvested after 2 days. The lysate was centrifuged at 4,000 x g for 15 minutes to pellet cell debris. The supernatant was then passed sequentially through 0.8, 0.45, and 0.2 μm filters. Polyethylene glycol 8000 (Sigma-Aldrich) was added to a final concentration of 10% wt/vol, incubated overnight at 4 °C, spun at ~25,000 x g for 1 hour and the pellet resuspended in 3 ml TE.

Copper electron microscope grids, carrying a Formvar film stabilized with carbon and glow discharged, were used to negative stain virus particles. Viral lysates were floated atop the grid and allowed to settle for 1 minute after which the grid was wicked dry. Grids were stained for 1 minute with a 5 μl drop of 2% uranyl acetate (pH 4) and wicked dry. Grids were viewed using a LEO 912 transmission electron microscope with a Proscan 2048 X 2048 pixel CCD camera. Virus size was measured using Olympus Soft Imaging System (SIS) software.

Nucleic acid characterization

PEG precipitated virus samples were digested with 50U DNase (Ambion Ribopure-Bacteria) for 30 minutes at 37 °C to remove contaminating host and bacterial DNA, and then extracted using a phenol:chloroform extraction (Thurber *et al.*, 2009). Nucleic acids were tested for bacterial contamination with polymerase chain reaction (PCR) using universal bacterial 16S rRNA primers (Lane, 1991) For detection of *Pseudo-nitzschia* genomic DNA, eukaryotic PCR primers 18SF and 5.8SR were used as in Hubbard *et al.*, 2008 to amplify the full-length ITS1 sequence. Only viral DNA that was free from bacterial and eukaryotic contamination was used for further analysis.

Viral nucleic acids were quantified using Quant-iT Assays (Invitrogen) to detect dsDNA, ssDNA, and RNA. First, viral nucleic acids were quantified each of the three Quant-iT Assays. Next, the Nucleic acids were digested with 0.67 U DNase (Ambion) and 3.33 U S1 nuclease (Promega) in 50 µl reactions at 37 °C for 1 hour. Controls consisted of reactions containing buffer and nuclease and buffer only served as negative controls. Digestions were performed in triplicate, and the nucleic acid concentration quantified with both the dsDNA assay and the ssDNA assay.

Viral nucleic acids were mechanically sheared using a Hydroshear (Digilab) to 1500 bp and ligated into pUC 2.4 plamids using the TOPO TA cloning kit. Chemically competent *E. coli* were transformed with the plasmids and plated on 50 µg kanamycin Luria brother agar plates. Plates were incubated at 37 °C for 24 hours. Colonies were counted and screened for inserts using PCR with M13 primers and running the resulting PCR products on an electrophoresis gel.

Genome sequencing and analysis

Cultures of *P. multiseriis* GGB1 and *Thalassiosira pseudonana* CCMP1335 were inoculated with the virus and lysed. Lysates were purified by sequential filtering and PEG precipitation and DNA was extracted and tested for contamination as described above. Purified viral DNA was converted to double-stranded DNA (dsDNA) with rolling circle amplification (Genomiphi). Viral dsDNA from the *P. multiseriis* culture was mechanically sheared into 1500bp fragments and clone libraries were constructed using the TOPO TA cloning kit (Invitrogen) using the manufacturers instructions. Insert DNA in plasmids from 384 colonies was Sanger-sequenced from both ends using the T7 and T3 primer sites. Sequence reads were trimmed for vector sequence and quality and reads that overlapped with their mates were assembled into contigs. After quality trimming, 475 sequences had an N50 of 713bp.

Viral DNA from the *T. pseudonana* culture was sequenced using PacBio resulting in 92,368 reads with an average length of 5,679bp. PacBio reads were assembled using the Heirarchical Genome Assembly Process v2.0 with quiver polishing using the default options. Contigs were assembled using Sequencher v4.9. To verify the assembly, Sanger sequencing reads were mapped to the PacBio contigs using Sequencher. Open reading frames (ORFs) were called using GeneMark.hmm v3.0.2 (Besemer and Borodovsky, 1997) and annotated based on the top 5 BLAST consensus (e-value = $1e-3$) with at least 50% sequence identity with hit sequences, and bit score >50 against nr (November 30, 2015). ORFs not meeting these criteria were labeled hypothetical.

Phylogenies of the polymerase B (polB), capsid, replication initiator, and helicase genes were constructed using RAxML v 8.0.23 (Stamatakis, 2012). Briefly, reference protein sequences were downloaded from GenBank and aligned with Muscle v 3.8.31 (Edgar, 2004). A

maximum likelihood tree was inferred from 20 starting trees using the amino acid substitution model models VTF for polB, RTREV for the capsid gene, WAGF for the replication initiator gene, and BLOSUM62F for the helicase gene.

Quantification of viral genomes

Genome segment-specific qPCR primers were designed using Primer3 (Rozen and Skaletsky 2000). Genome fragment 1 was targeted by the primers G1H-F: 5'-TAGCGATGGACAGCAAACAG-3' and G1H-R: 5'-AGGAGCGATTTGACGTGTTC-3'. Genome fragment 2 was targeted by the primers G2e-F: 5'-ACCGACAAAACAGGAGCATC-3' and G2E-R: 5'-TCCGCAATCTCTTGACTGTG-3'. Primers were tested *in silico* for cross amplification of untargeted genome regions. Standards for qPCR were generated by PCR amplification of viral DNA consisting of 95 °C for 5 minutes followed by 30 cycles of 95 °C for 30 s, 60 °C for 45 s, and 72 for 60 s. Reactions consisted of 1X reaction buffer, 1.5mM MgCl₂, .8 mM dNTPs, 1µM forward and review primer, 10ng viral template, and 1 U *Taq* polymerase in 20 µl final volume. Amplicons were purified using Agencourt AMPure XP beads (Beckman Coulter) and ligated into pCR2.1 vector and cloned into *Escheria coli* using the TOPO TA Cloning Kit. Positive colonies were grown overnight at 37 °C in Luria broth medium and the plasmids harvested using Plasmid Miniprep Kit (Qiagen). Isolated plasmids were linearized with *XbaI* (New England Biolabs) at 37 °C for 2 hours. Linearization was confirmed with gel electrophoresis, and the linearized plasmid was cleaned with AMPure beads. DNA concentration was quantified with a Qubit HS DNA assay and used to calculate the number of copies µl⁻¹ used in the standards.

qPCR consisted of 20 μ l reactions with 5 μ l of sample template or linearized plasmid standard, 300 nmol forward and reverse primer, 0.5 μ l ROX reference dye (Invitrogen), and 10 μ l of iQ Supermix (BioRad). Reactions were carried out in a ABI One Step Plus Real Time Thermocycler with an initial incubation at 95 °C for 3 minutes followed by 40 cycles of 95 °C for 30 s, 58 °C for 45 s, and 72 for 60 s. A step-wise melt curve followed the cycling conditions to verify a single melt peak. A dilution series of standards and no-template controls were amplified at the same time as unknown samples and copy numbers in unknown samples were calculated relative to the standard curve by ABI One Step Plus software.

Verification of viral genome segment relationship

Axenic *T. pseudonana* CCMP 1335 cultures were inoculated in 15 independent experiments with a 1:2 dilution series of viral lysate, with each dilution having 8 replicates. Experiments were monitored in 48 well microplates (Corning) for 3 weeks. Most probable number (MPN) tables determined the number of viruses in lysed wells from the most dilute virus inoculum. DNA from these wells was extracted using a phenol-chloroform extraction and both genome segments were quantified using qPCR.

Viral lysate, 4ml, was adjusted with cesium chloride to 1.12 g ml⁻¹ and loaded onto two different columns, one with density gradients with 1 ml layers of 1.2, 1.3, 1.4, 1.5, and 1.7 g ml⁻¹ and the second with 1 ml layers of 1.25, 1.35, 1.45, 1.55, and 1.7 g ml⁻¹ in thin walled ultracentrifuge tubes (Beckman). The columns were centrifuged at ~80,000 xg (22,000rpm) for 2 hours at 4 °C in a Beckman SW 41 Ti rotor. Each layer (1mL) was carefully extracted using a 20 gauge needle and syringe. Viral DNA was extracted as above. The abundance of each genome segment was quantified using qPCR.

Host range

Algal cultures in supplemental table 2 were grown to mid-exponential phase. Seven serial ten-fold dilutions of the virus stock (100 µl) were inoculated into 900 µl algal cultures in quadruplicate in 48-well plates. Four control wells used sterile filtered and autoclaved natural seawater as inoculum. 1 ml algal culture was preserved with 40 µl acidified Lugol's solution at time 0 for cell counting on a Sedgwick Rafter slide or haemocytometer to determine virus to host ratios (Wildlife Supply Company). Infected cultures were monitored via fluorescence until control cultures declined, approximately two weeks.

Virus to host ratio determination

The infectious units per volume for one-step growth curves were determined by a fine-scale dilution series. A range of viral lysates, from 50% to 0.1% of total volume, was inoculated in quadruplicate into exponentially growing axenic *P. multiseriis* PC9 or axenic *T. pseudonana* CCMP 1335. Control wells had filtered f/2 medium added to 10% of the total volume. Chlorophyll-a fluorescence measurements were taken every four hours until the cultures had lysed as defined by a decrease of half the maximum fluorescence. At t=0, 1ml of culture was preserved for cell counts in 40 µl acidified Lugol's solution. The appropriate viral to host ratio was predicted to lie between the dilution that exhibited a uniform rate of decline and the dilution in which the rate of decline was variable over the infection, indicating the entire culture was not infected. At least 300 cells were quantified by counting on a Sedgwick-Rafter or haemocytometer (Wildlife Supply Company). One milliliter of the virus stock solution was gently filtered onto a 0.02 µm filter (Whatman), stained for 15 minutes with a 2X concentration

of SYBR gold, and visualized in the FITC channel using a Nikon Eclipse 80i epifluorescent microscope and Photometrics Cool Snap HQ² camera (Thurber *et al.*, 2009). For virus counts, 10 random fields per filter were captured at 1000X magnification and counted.

One step growth curve

Triplicate exponentially growing 30 ml cultures of axenic *P. multiseriis* PC9 or axenic *T. pseudonana* CCMP 1335 were inoculated with either the working stock viral lysate at the appropriate concentration for that strain or control lysate that had been heated at 90 °C for 15 minutes and UV irradiated for 15 minutes at the same volume. In all experiments, the cultures were regularly sampled for cell counts, and virus counts. Five hundred µl of culture was fixed with paraformaldehyde to a final concentration of 2%, and viruses were counted using epifluorescent microscopy as detailed above. For diatom counts, 10 random fields per filter were counted at 100x magnification, with unlysed diatoms detected by the fluorescence of an intact nucleus. Both genome segments were quantified with qPCR as described above.

In the *P. multiseriis* PC 9 experiment, samples from one replicate of the infected cultures were fixed with 1% glutaraldehyde and stored at 4 °C before DNA extraction. In the *T. pseudonana* experiment, samples from each infected and control replicate were first passed through a 1.2 µm filter. DNA from the free virus containing filtrate was then extracted.

Pseudo-nitzschia culture isolation and genotyping

Pseudo-nitzschia cultures were isolated from 20 µm mesh net tow samples from Penn Cove, WA (48°13'24N 122°41'14W), Golden Gardens, WA (47°41'27N 122°24'16W), East Sound, WA (48°40'49N 122°53'57W), Sequim, WA (48°40'12N 123°02'33W), Sunset Beach,

OR (46°05'53N, 123°56'43W) and Newport Beach, CA (33°35'54N 117°54'03W) by micropipetting single cells. Isolates were deemed uni-algal after 3 transfers where only one cell type was observed based on light microscopy. For ITS1 sequencing, cultures were collected on a 2 µm filter and DNA was extracted using a DNeasy Plant Mini Kit (Qiagen). The ITS1 region was amplified using primers 18SF and 5.8SR (Hubbard et al., 2008). PCR products were purified and sequenced at University of Washington Department of Biochemistry DNA Sequencing Facility. Sequences were identified taxonomically based on greater than 97% similarity to sequences of SEM verified cultures in GenBank. MUSCLE (Edgar, 2004) was used for alignments and pairwise percent identity calculations. Sequences are deposited in Genbank under accession numbers KF015190-KF015204.

Chapter 2

Pseudo-nitzschia challenged with co-occurring viral communities display diverse infection phenotypes

2.1 Abstract

Viruses are catalysts of biogeochemical cycling, architects of microbial community structure, and terminators of phytoplankton blooms. Diatoms are eukaryotic phytoplankton that contribute to carbon export and productive food webs in the ocean. The impact of viruses on diatom abundance and community composition is unknown. Diatom-virus dynamics were explored by sampling every month at 2 coastal and estuarine locations in Washington state, USA resulting in 41 new isolates of the pennate diatom *Pseudo-nitzschia* and 20 environmental virus samples. We conducted a total of 820 pair-wise crosses of the *Pseudo-nitzschia* isolates and viral communities. Viral communities infected *Pseudo-nitzschia* isolates in 8% of the crosses and were most susceptible to infection when the host and viral communities were isolated from the same sample. Isolates ranged in their permissivity to infection with some isolates not infected by any viral samples and others infected by up to 10 viral communities. Isolates that were infected by the most viral communities yielded the highest viral titers (as high as 16000 infectious units ml⁻¹). Titers were host dependent, as titers for one viral sample on 8 different hosts spanned 4 orders of magnitude. A comparison of *Pseudo-nitzschia* Internal Transcribed Spacer 1 sequences revealed multiple subgroups of genetically identical hosts that were differentially infected. Monospecific blooms of *Pseudo-nitzschia* were composed of multiple viral infection phenotypes. This phenotypic diversity may be a defense against viral termination of diatom blooms. The interactions between *Pseudo-nitzschia* and the viral communities highlight the

diversity of diatoms and emphasize the complexity and variability of diatom-virus dynamics in the ocean.

2.2 Introduction

In the ocean, viral infection links microbial community structure, biogeochemical cycling, and microbial evolution (Breitbart, 2012). Viruses regulate marine phytoplankton communities by impacting host abundance and diversity through cell lysis (Weitz and Wilhelm, 2012). Viruses and their hosts are thought to cycle dynamically, with encounter rates favoring infection of dominant microbial taxa, which are removed due to lysis and then supplanted by new microbial populations that fill the vacant ecological niche (Thingstad, 2000). These ‘Kill-the-Winner’ dynamics have important, but often cryptic scales of interaction are thought to occur at varying temporal, spatial, and taxonomic levels (Thingstad 2000; Thingstad et al. 2015). Understanding the scales of host-virus interactions is critical for accurately quantifying viral contributions to microbial mortality.

Host permissivity to viral infection and viral host range are important mechanisms that underlie kill-the-winner dynamics and directly affect the success of viruses in the ocean. Cultured marine host-virus systems suggest that viruses range from generalists to specialists, while hosts range in their susceptibility to viral infection from highly permissive to resistant; the hierarchical ordering of these properties in hosts and viruses is known as nestedness (Flores et al. 2011). Additionally, hosts and viruses can coevolve to form modules defined by viruses capable of infecting only hosts within a given module. These patterns have been observed in wild host-virus communities. Phage isolated from a transect across the Atlantic were most infective of co-occurring host bacteria and formed modules by geographic separation (Flores et al. 2012). On the

other hand, Waterbury and Valois (1993) demonstrated that *Synechococcus* phage titers over two years at the same location were not inversely correlated with *Synechococcus* abundance and thus were unimportant in controlling co-occurring cyanobacteria populations. These divergent results may be due to the small sample sizes of isolation based studies and the timing of host population cycling: isolated hosts may be in the process of being removed by their co-occurring viruses, or they may represent the supplanting microbial population that is resistant to the dominant viruses in the water. Thus, co-occurring resistance and susceptibility fluctuate in Kill-the-Winner dynamics such that both scenarios are plausible.

The dramatic boom and bust life cycles of eukaryotic phytoplankton pose both challenges and opportunities for viruses. Eukaryotic phytoplankton blooms reach high cell densities, are often composed of few species, which may be excellent conditions for viral infection (Brussaard 2004; Armbrust 2009). Viral termination of blooms has been observed in eukaryotic phytoplankton–virus systems such as *Emiliana*, *Phaeocystis*, *Heterosigma*, *Aureococcus*, and *Micromonas* (Bratbak et al. 1993; Cottrell and Suttle 1995; Tarutani et al. 2000; Gobler et al. 2004; Baudoux et al. 2006; Vardi et al. 2009, Lehahn et al., 2014). Under non-bloom conditions, viruses of eukaryotic phytoplankton must survive times of host scarcity since the propagation of viruses relies on contact rates between hosts and viruses. Viruses may rely on alternative strategies of propagation such lysogeny and latent infections (McDaniel et al. 2002, Thyrraug et al. 2003), or sequestration in sediments (Tomaru et al. 2011a) during these times. Ultimately, the reduction of viral abundance during times of host scarcity may be a mechanism that eventually allows phytoplankton to increase in abundance without immediate infection by viruses.

Diatoms are a group of diverse and ubiquitously distributed eukaryotic phytoplankton that exhibit a boom-and-bust life cycle. They dominate primarily in temperate coastal and polar

oceans where they can form massive blooms, which fuel carbon export and productive food webs (Nelson et al. 1995). *Pseudo-nitzschia* is a cosmopolitan genus within the diatoms consisting of 37 described species (Lelong et al. 2012; Trainer et al. 2012). *Pseudo-nitzschia* is particularly known for the ability to produce the neurotoxin domoic acid, which can be biomagnified through food webs and can disrupt ecosystems and create public health concerns (Bates et al. 1989; Scholin et al. 2000). Toxin production varies by species (Trainer et al. 2012), underscoring the importance of *Pseudo-nitzschia* community structure for understanding toxic bloom formation.

The first diatom viruses were isolated and characterized only a decade ago (Nagasaki et al. 2004) and since then the number of diatom viruses has grown to 15, isolated on 4 genera, the centric diatoms *Rhizosolenia*, *Chaetoceros*, and the pennate diatoms, *Asterionellopsis* and *Thalassionema* (Bettarel et al. 2005, Eissler et al. 2009, Kimura and Tomaru, 2015). All diatom viruses have fallen into two groups based on their nucleic acid content, either single stranded RNA or single stranded DNA. This is in contrast to the majority of model eukaryotic phytoplankton – virus systems that involve large double stranded DNA viruses, primarily from the Phycodna- and Megaviridae families (Nagasaki and Bratbak 2010; Moniruzzaman et al. 2014). Furthermore, the host ranges of diatom viruses are narrow. Only a few diatom viruses, such as CdebDNAV and RsRNAV, have been shown to infect multiple hosts, all within the same species (Nagasaki et al. 2004; Tomaru et al. 2008; Kimura and Tomaru 2015).

Diatom viruses are genomically and functionally different than other viruses that infect other photosynthetic marine eukaryotes. Diatoms exhibit similar boom-and-bust dynamics other photosynthetic eukaryotes. Therefore are the dynamics between diatoms and their viruses similar in their capacity to control diatom populations and terminate blooms? Diatom viral infectivity

based on titers of virus concentration performed on one strain of *Chaetoceros gracilis* fluctuated seasonally, reaching a maximum during the early spring when treated with environmental viral communities from Chesapeake Bay (Bettarel et al. 2005). Similarly, viral infection of one strain of *Chaetoceros tenuissimus* consistently peaked in the late summer and fall from water and sediment samples taken from coastal Japan (Tomaru et al. 2011a). Additionally, Tomaru et al. (2011a) designed qPCR primers that were specific to *C. tenuissimus* and *C. salsugineum*, both of which have been used to isolate viruses (Shirai et al. 2008, Nagasaki et al. 2005). Host and environmental virus abundance were monitored over the span of several years with qPCR and titers, however, no correlation between fluctuations in the *Chaetoceros* species abundance and virus abundance were found (Tomaru et al. 2011a). While only three diatom cultures total have been tested, these results highlight an incongruity between diatom and virus dynamics, which may be occurring on unknown scales.

In this study, we assessed the temporal and spatial scales of diatom–virus interactions and quantified patterns of infection and host permissivity. *Pseudo-nitzschia* were isolated and challenged with viral communities taken every month from two locations in the Pacific Northwest. The resulting patterns in infectious crosses between *Pseudo-nitzschia* and the virus communities were used to understand how viral infection changed between locations and in time, how infection patterns correlated with host genotype, and how these interactions might shape *Pseudo-nitzschia* communities in the field.

2.3 Methods

Environmental virus sample collection and purification

Samples were collected at Penn Cove, Washington (48.2397, -122.6795) and Grays Harbor, Washington (46.7625, -124.0898) (figure 1) monthly from April 2013 to April 2014 except from November to February, when sampling occurred at Penn Cove in November and January and at Grays Harbor in December and February. Approximately 15L of surface water was filtered through triplicate 3.0 μm and 0.2 μm 147mm polyethersulfone filters (Millepore) with a peristaltic pump within 2 hours of sampling. The filters were frozen at -80°C for molecular analysis. The viruses in the filtrate were precipitated by adding iron chloride (1g L^{-1}) and incubating for 12 hours at 13°C in the dark (John et al. 2011). The iron-precipitated viruses were collected by filtering on to 2.0 μm and 0.2 μm 147 polycarbonate filters (Millepore). The viruses were resuspended from both filters by incubating them with 0.2M ascorbate-0.25M EDTA-Mg²⁺-0.25M Tris-HCL for at least 24 hours with periodic shaking (John et al. 2011). The resuspended viruses were purified to remove Fe-EDTA complexes by adding 10% poly ethylene glycol (PEG) and 2% NaCl final concentrations and incubating at 4°C for 24 hours. The samples were then spun at 12000 xg for 20 minutes at 4°C to pellet the viruses. The supernatant was removed and the pellet washed three times with modified SM buffer (0.4M NaCl, 0.02M MgSO₄, 0.05M Tris, pH 7.5). Washing and pelleting were repeated twice. The PEG was removed according to Colombet and Sime-ngando (2012) by adding 2M KCl and incubating the samples on ice and removing the supernatant. The purified virus samples were stored at 4°C .

Pseudo-nitzschia community analysis

Subsections of the 3.0 μm filters collected during sampling events were extracted using a Qiagen DNeasy minikit. The Internal Transcribed Spacer 1 (ITS1) was amplified for Automated Ribosomal Intergenic Spacer Analysis (ARISA) using triplicate PCR amplifications of the

purified DNA of environmental DNA or culture DNA using primers PnALLF and 6FAM-PnALLR for 34 cycles with conditions described in Hubbard et al. (2008). Reactions were purified with a Qiaquick PCR Purification Kit, and sequenced at the University of Washington Fred Hutchinson Research Center. Two blanks, one water and one negative control from the ARISA PCR, were used to establish a noise baseline for each run. ARISA reactions were confirmed to be in linear amplification phase at cycle 34 for semiquantitative analysis using iQ SYBR green supermix (BioRad) with the same DNA and primer concentrations and cycling conditions as the reactions above.

Electropherograms of the ARISA runs were analyzed using PeakScanner (Life Technologies). Peaks were called if they were above a 50:1 signal to noise ratio, between 120 and 300 bp in length, and represented at least 3% of the total fluorescence. Peak area was summed over two base pair bins and divided by total fluorescence, which gave a relative abundance. Peaks were identified using predicted ITS lengths from the *Pseudo-nitzschia* isolates as well as from reported ITS lengths in Hubbard et al. 2008 and Hubbard et al. 2014. The resulting community profiles were analyzed using the statistics package Primer-6 (Clarke and Warwick 2001). Similarity between community profiles was calculated using both Bray-Curtis and Jaccard matrices. Matrices were clustered and tested for significance using a SIMPROF test.

Isolation and identification of Pseudo-nitzschia

A 10 μm net was hand-towed through the water for approximately 5 minutes during each sampling event. Single chains of *Pseudo-nitzschia* were picked with a pipette and purified through three washes with f/20 medium. All cultures in this study were maintained in f/2 medium + silica at 13 °C at an irradiance of 26.7 $\mu\text{mol photons m}^{-2} \text{ s}^{-1}$ with cool white

fluorescent illumination on a 16:8 light-dark cycle. Isolated strains were verified by light microscopy to be unialgal but not axenic.

Cultures were grown to mid-exponential phase and centrifuged at 5000 x g for five minutes to pellet cells. DNA was extracted with a DNeasy plant minikit (Qiagen) according to the manufacturer's protocol. The ITS1 amplification was based on the methods in Hubbard et al. (2008). PCR primers Euk-18SF and Euk-5.8SR were used to amplify the full-length ITS1 sequence of the *Pseudo-nitzschia* strains. PCR amplicons were purified with Qiaquick PCR Purification Kit and sequenced using Euk-18SF and Euk-5.8SR primers with Sanger sequencing at Genewiz (Seattle, WA) and University of Washington High Throughput Sequencing Center (Seattle, WA). Sequences were identified taxonomically based on greater than 97% sequence identity to sequences of scanning electron micrograph (SEM) verified cultures in GenBank. MUSCLE (Edgar 2004) was used for alignments and pairwise percent identities calculations. Sequences have been deposited in GenBank under accession numbers KR053126-KR053164.

Infections of Pseudo-nitzschia isolates with environmental samples

Pseudo-nitzschia culture growth was monitored via chlorophyll-a fluorescence on a Turner AU-10 fluorometer. All infection crosses were performed in 48 well plates (Corning) in replicates of 5 with 1 ml exponentially growing culture, between 10-30% of their maximum relative fluorescence units, and 20 µl of purified environmental virus sample. For each cross, a control culture was amended with 20 µl f/2 media. Additionally, control *Pseudo-nitzschia* cultures were inoculated with 20 µl of virus samples that were UV irradiated (100 cm from a Philips TUV 36 T5 SP UV bulb) for 15 minutes. Crosses were maintained under the same temperature and light conditions as above. Culture growth in well plates was measured via

chlorophyll-a fluorescence on a Spectramax M2 Plate Reader (Molecular Devices). Treated wells that declined by more than half of their maximum fluorescence while control cultures were still healthy were scored as infected.

10-fold dilutions, ranging from 10^0 - 10^{-7} , of the environmental virus samples were inoculated into 1 ml cultures of exponentially growing *Pseudo-nitzschia* in replicates of 5. The growth and death of the *Pseudo-nitzschia* in titer experiments was monitored as above via chlorophyll-a fluorescence. Concentrations of infectious units per unit volume were determined based on most probable number (MPN) tables. Infectious units ml^{-1} seawater were calculated assuming 100% retention of viral infectivity during filtering, flocculation, and storage. To get infectious units ml^{-1} seawater, MPN values were multiplied by the 10^6 to account for concentration of viruses from whole water to the final viral community sample.

Statistical analysis of infection networks

Statistical structure of the infection network generated from the crosses was tested using the BiMat package developed by Flores et al. (2014) in MatLab. Tests of modularity, using the Adaptive Brim algorithm, and nestedness, using NODF (nestedness measure based on overlap and decreasing fills) were compared to 10000 equiprobable randomized networks for statistical significance. Correlation between modules and ITS1 genotype, location, time, and infection permissivity were tested by comparing the Shannon diversity index of modules based on the predetermined categories to modules with randomly assigned categories (Flores et al. 2014).

2.4 Results

Environmental conditions and Pseudo-nitzschia community structure

Samples for viral communities and *Pseudo-nitzschia* isolates were taken every month from April 2013 to April 2014 (except for December and February in Penn Cove and November and January in Grays Harbor) at two sites (figure 1). Penn Cove is a shallow (20m depth) inlet in the Puget Sound estuary and Grays Harbor is located on the Pacific coast of Washington State. In total, 20 environmental virus communities were sampled and 41 *Pseudo-nitzschia* strains were isolated. *Pseudo-nitzschia* were isolated successfully during summer months when water temperatures were warm (13-17 °C), nutrient concentrations were low ($<6\mu\text{M NO}_3^-$) (figure 2a and b). Nitrate concentrations were positively correlated with phosphate and silicate concentrations at Grays Harbor and Penn Cove, respectively ($p<0.001$).

Eight species of *Pseudo-nitzschia* were isolated and identified based on $\geq 97\%$ sequence identity of the ITS1 region to SEM verified *Pseudo-nitzschia* strains: *P. pungens*, *P. multiseriata*, *P. australis*, *P. delicatissima*, *P. americana*, *P. hasleana*, and two unknown species. *P. pungens* was isolated most frequently in 8 samples and comprised 28/41 strains isolated. Out of 22 isolates from Penn Cove, 21 isolates were *P. pungens* and *P. multiseriata* (figure 2a), while out of 20 isolates from Grays Harbor, 17 isolates were *P. pungens*, *P. australis*, and *P. delicatissima* (figure 2b). Two strains, *P. sp.* GH10 and *P. sp.* PC33, were unable to be assigned species identification based on their ITS1 sequence. *P. sp.* GH10 ITS1 was 88% similar to *P. seriata* and had a 138 base pair ITS1 fragment when amplified using *Pseudo-nitzschia* specific primers. The full length ITS1 region of *P. sp.* PC33 was unable to be amplified. Both isolates were confirmed via light microscopy to be *Pseudo-nitzschia*.

Pseudo-nitzschia community composition at the two sites was determined by ARISA targeting the *Pseudo-nitzschia* ITS1 region (Hubbard et al. 2008). *Pseudo-nitzschia* were detectable in 15 of 20 samples (figure 2c and d). *Pseudo-nitzschia* communities from both Grays

Harbor and Penn Cove throughout the year were composed of 3 or more species except for a monospecific bloom of *P. pungens* at Penn Cove in June (figure 2c). *P. pungens* and *P. subpacific*a were the most common species detected in the entire dataset, present in 4 of 7 samples from Penn Cove and 4 of 8 samples from Grays Harbor. *Pseudo-nitzschia* communities did not cluster significantly by location or time.

Infection of Pseudo-nitzschia host strains

The 41 *Pseudo-nitzschia* isolates were crossed with the 20 environmental virus samples in replicates of 5 to create an infection network of 820 infectious crosses. In total, 68 *Pseudo-nitzschia* - virus community combinations showed signs of infection. *Pseudo-nitzschia* isolates inoculated with UV irradiated viral communities showed no signs of infection compared to medium-only controls. Overall 8% of crosses between *Pseudo-nitzschia* and virus communities were infective (figure 3). Hosts isolated from Penn Cove were infected by virus communities from Grays Harbor, and vice versa. Hosts and viruses that came from different times and locations were not significantly less infective than the total average. Crosses of *Pseudo-nitzschia* and virus communities from the same time and location resulted in infection at double the overall infection rate (Chi-square $p=0.009$) (figure 3).

Pseudo-nitzschia isolates were not infected uniformly in the initial survey of the *Pseudo-nitzschia* hosts crossed with the viral communities (figure 4). Thirteen host strains showed no detectable signs of infection from any environmental virus community. The 28 strains were infected more than once, and ranged from being infected by one viral community to up to 10 viral communities. Five *Pseudo-nitzschia* hosts, *P. pungens* GH29, *P. pungens* PC45, *P. australis* GH31, *P. pungens* GH23, and *P. pungens* GH20 were infected by 5 or more viral

communities, accounting for 48% of the total infectious crosses observed. Frequently, not all replicates died within one host-virus community cross (figure 4). Based on most probable number calculations in this survey, bounds of infectious units could be put on infectious crosses where between 1 – 4 replicates died (e.g. 1 replicate death = 2-11 infectious units ml⁻¹, 4 replicates death = 13-34 infectious units ml⁻¹). The samples that resulted in infection in all 5 replicates had titers that were at least 23 infectious units ml⁻¹ but the upper bound of infectious units was unknown. Hosts with more infections had infectious crosses where more replicates died (linear regression R² = 0.536, p<0.01). The most infected host, for example, *P. pungens* GH20 had 8 out of 10 infectious crosses where all five replicates died (figure 4). Titers were performed to quantify the infectious units in these highly infectious crosses.

Host specific viral titers

More detailed changes in viral abundance over time were quantified by performing titers on *Pseudo-nitzschia* strains that represented a range of infection phenotypes. Host strains *P. pungens* PC45 and *P. pungens* GH20 were infected by 5 and 11 of the 20 viral communities and represented hosts with high numbers of infections. *P. sp* 1 GH10, *P. pungens* GH30, and *P. pungens* GH34 were infected by 2 or 3 of the 20 viral communities and were defined as representative of moderately infected hosts. *P. pungens* PC62, *P. pungens* PC40, and *P. australis* GH28 represented hosts with low numbers of infections. Viral titers were determined for each of these 9 hosts with every viral community. Measures of viral abundance varied by time and by host (figure 5a and b). Host strain *P. pungens* PC45 had high titers with three titers above 300 infectious units ml⁻¹ that occurred predominantly during summer months. The highest viral infectivity of over 10⁴ infectious units ml⁻¹ seawater was observed on this strain crossed with the

July Penn Cove viral community (figure 5a). Interestingly, PC45 was isolated from the same water sample. However, strain *P. pungens* PC40, also isolated at the same time from the same water sample as PC45 had four orders of magnitude lower viral abundance when crossed with the same July Penn Cove virus community (figure 5a). This viral community did not infect the other 6 host strains on which titers were performed. In contrast with the observed high viral titers on PC45 in the summer at both locations, strain *P. pungens* GH20 had the highest titers in the fall and winter months at both locations. Host strains that were infected by the widest variety of viral samples (figure 4), such as PC45 and GH20 also had the highest maximum observed titers, 16000 and 540 infectious units ml⁻¹, respectively, compared with less infected strains like PC40 and GH28, which had lower maximum titers, 2 and 7.8 infectious units ml⁻¹ respectively.

Patterns of viral infection by host genotype

The *Pseudo-nitzschia* hosts were grouped by ITS1 based species identification, ITS1 percent sequence identity, and according to the number of infectious crosses with the viral communities (figure 6). Five groups of isolates had 100% nucleotide identity at the ITS1 region (figure 6). Sixteen *P. pungens* strains with 100% identical ITS1 sequences consisted of 12 infection phenotypes. A second group of 8 *P. pungens* strains with a different ITS1 sequence consisted of 6 infection phenotypes. The phenotypes ranged from infected by multiple viral communities to not infected at all. This same pattern of diverse infection phenotypes within groups of isolates that 100% identical ITS1 sequences was observed in *P. multiseriata* (3 infection phenotypes in 4 strains), *P. australis* (2 infection phenotypes in 3 strains), and *P. delicatissima* (2 infection phenotypes in 2 strains) (figure 6). In fact, of the 28 strains that were infected by at

least 1 viral community, only two strains *P. pungens* GH 14 and *P. americana* GH39 displayed the same infection phenotype, and they belonged to different species.

Pseudo-nitzschia-virus infection network

The interactions between the *Pseudo-nitzschia* and the viral communities were tested to see if there were statistically significant patterns of nestedness and/or modularity by comparing patterns in the host-virus network to 10^5 randomized equiprobable null models. First, the network was anti-nested (nestedness value (NODF) = 0.1023, z-score = 3.4193, percentile = 99.83, figure 7a). Second, the interactions between hosts and viruses occurred in modules (modularity value (Adaptive Brim Qb) = 0.5133, Z-score = -2.3491, percentile = 0.95, figure 7b). Reorganization to optimize modularity suggested 6 statistically significant modules, 3 of which had at least 12 infectious interactions between viruses and hosts while the other three had less than 5 interactions. Nested patterns can exist within modules, but only module 3 was significantly nested (Qb=0.53061, Z-score= 2.1241, percentile= 96.64). Interactions within modules did not group by location, time of sampling, ITS genotype, or host permissivity.

2.5 Discussion

Host specific viral interactions

Pseudo-nitzschia strains ranged in their susceptibility to the viral communities sampled in this study with some hosts showing no signs of infection from any of the viral communities tested while others were infected by multiple different communities. Hosts that were susceptible to more viral communities had higher titers than less infected strains (figure 4, 5). As seen with the July Penn Cove viral sample, for example, different hosts gave widely different titers ranging

from over 16,000 infectious units ml⁻¹ to below the limit of detection (figure 5a).

Prochlorococcus and its phage exhibit similar trends of differential susceptibility and titers by host, which are the result of different host specificities of infecting viruses (Dekel-Bird et al. 2014). Furthermore, different hosts enable the isolation of different viral assemblages (Dekel-Bird et al. 2014), underscoring the need for isolating viruses on a range of hosts in order to capture a better picture of viral diversity.

There are caveats to using titers to quantify infection of algae. The use of only permissive hosts for host titers and virus isolation may skew data of viral abundance and composition. Also, viruses may change their infection dynamics based on the number of viruses inoculated into a culture and infecting a host (Gutierrez et al. 2010), potentially leading to different infection dynamics. Finally, bacteria, which may be algacidal, may pass through a 0.2 µm filter (Lee et al. 2010) and lyse algal cultures. Ultimately, we were unable to differentiate between viral lysis and other pathogens.

The patterns of host specific interactions seen in the viral infectivity or titers did not follow host genotype determined by ITS1 sequence, as strains with identical ITS sequences displayed widely varying infection phenotypes (figure 6) and titers (figure 5). Similarly, isolated diatom viruses have been observed to infect some strains but not others within one species (Nagasaki et al. 2004; Tomaru et al. 2008; Kimura and Tomaru 2015). The variation by host seen here and in isolated diatom viruses suggest that trying to survey the impact of viruses on diatom communities using traditional phylogenetic markers will most likely be inconclusive. There is no known genetic marker diagnostic of infection phenotype in diatoms.

Time and location of host and viral community origin was the best predictor of infectivity with co-occurring hosts and viruses being the most infective. A similar study using 10

Synechococcus isolates and 10 phage isolated from the same water as the hosts, found that hosts were more resistant to co-occurring viruses (Waterbury and Valois 1993). However, Flores et al. (2012) analyzed the interactions between 286 bacteria and 215 viruses isolated from a transect across the Atlantic and found that phages were more likely to kill hosts from the same location. In the framework of ‘Kill-the-Winner’ dynamics, both co-occurrence and resistance fluctuate dynamically as well (Thingstad 2000). The rate that new hosts fill vacant niches caused by viral infection may determine how frequently resistance or co-occurring infectivity is observed. Niches that are filled quickly by resistant taxa would result in a higher chance that sampling a host that is resistant to a virus from the same water. Consequently, fine temporal scale sampling is needed to resolve changing microbial populations. Additionally, host identification using markers that distinguish between taxa based on viral infection phenotype are needed to fully reveal the dynamic cycling of hosts and viruses in the environment.

Interestingly, viral communities from Grays Harbor could infect hosts from Penn Cove and vice versa (figure 3). Furthermore, the rates were no different from viruses infecting hosts at the same location, but at different times. Additionally, every virus community sample could infect at least one host. One explanation for these results may be a connectivity between viral and host populations in the Puget Sound and on the Washington coast. Based on hydrographic models of Puget Sound, surface water from Whidbey Basin, where Penn Cove is located, could reach the Washington coast in 15-30 days, while deep water from the coast would reach Whidbey on the order of 2 months at least (Babson et al. 2006). Thus, the transport of water between Puget Sound and the Washington coast occurs on temporal scales roughly similar to the frequency we sampled each individual location.

Anti-nestedness and viral host range

A major question about the ecology of diatom infecting viruses is, given the dramatic bloom and bust life style of diatoms, how are viruses propagated and successful? *Pseudo-nitzschia* communities sampled over the year became so rare that they were undetectable with ARISA 20% of the time, particularly during winter months (figure 2c and d). *Pseudo-nitzschia* ARISA can detect *Pseudo-nitzschia* at concentrations as low as 1 cell L⁻¹ (Hubbard et al. 2014). Yet viruses from those months were infective of *Pseudo-nitzschia* isolates. There are two explanations for this disconnect between host abundance and viral infectivity. First, sediment samples have consistently been shown to have high viral infectivity from diatom viruses (Tomaru et al. 2011a). The sediments could be seed bank for diatom virus communities. Sediment resuspension or entrainment with upwelling, which occurs during turbulent mixing events particularly in the winter and spring in the Pacific Northwest (Hickey and Banas 2008), could be a mechanism for re-inoculating surface waters with viruses. This would allow diatom viruses to ‘overwinter’ during times of host scarcity. Second, diatom viruses may have broader host ranges (beyond a single species) than have been detected in culture studies to date, allowing for propagation on a wider range hosts to maintain their abundance in the water column.

The observed infections of *Pseudo-nitzschia* were the result of the integrated infectivity of the entire viral community. Typically, virus-host networks are composed of virus isolates crossed with isolated hosts (Weitz et al. 2012), resulting in a network where both the viral isolates’ host ranges and host susceptibility is known and can then be tested for evolutionary and ecological patterns between hosts and their viruses. Here, the composition and abundance of viruses in the environmental communities was unknown. A high titer on a specific strain could be the result of many viruses at low abundance or one virus at high abundance. Similarly, the

infection pattern seen in any one viral community could be due to one virus with a broad host range or many viruses with narrow host ranges. The infection patterns by each viral community were highly variable from month to month. Statistical analyses indicate that the infection network is anti-nested (figure 7a). In contrast to nested networks, anti-nested networks are interaction poor, with hosts increasing incrementally in their number of interactions but viruses not following the incremental increase typical of nested patterns. Therefore, in order to have increasing host interactions, the interactions must come from a significantly more diverse set of viruses. Diversity in the viral communities could also be a function of the error prone RNA-dependent RNA polymerases and rolling circle replication mechanisms used by ssRNA and ssDNA viruses, respectively, that result in high mutation rates which alter viral host ranges (Duffy et al. 2008; Nakayama et al. 2013). The connection between host range, diatom virus diversity, and community composition is a critical, but unknown factor in diatom-virus ecology.

Diatom virus modulation of Pseudo-nitzschia communities

Diatoms are one of the most important groups phytoplankton in the ocean because of their ability to form massive blooms, the fate of which is critical to biogeochemical cycling (Smetacek, 1999). Over the year sampled in this study, *Pseudo-nitzschia* communities were diverse and transient. They were similar in composition and diversity to communities found previously throughout the Pacific Northwest in other years using the same ARISA technique (Hubbard et al. 2008, 2014). Diatom communities have been shown to be composed of populations of cells that are genetically distinct but nearly identical at the 18S, 5.8S, and ITS1 regions (Rynearson and Armbrust 2005). Thus the genetic diversity of these *Pseudo-nitzschia* communities is probably underestimated. On three occasions, June Penn Cove, September Penn

Cove, and August Grays Harbor, a single species (*P. pungens*, *P. cuspidata*, and *P. pungens* respectively) composed more than 60% of the *Pseudo-nitzschia* community. However, the *P. pungens* dominated community in August at Grays Harbor, for example, was composed of at least 4 different host phenotypes that were indistinguishable based on sequencing or fingerprinting (such as ARISA) of taxonomic markers. Based on the interactions between *Pseudo-nitzschia* isolates and the viral communities, we suggest these periods of single species dominated communities were actually much more phenotypically diverse.

The mechanisms that could lead to these diverse phenotypes remain unknown in diatoms. Bacteria may mediate resistance to infection in diatoms. For example, certain species of bacteria added to axenic cultures *Chaetoceros tenuissimus* prevented total lysis of the culture by the CtenRNAV (Kimura and Tomaru 2014). Differential viral resistance in *Prochlorococcus* was a result of genetic diversity found in the hypervariable regions of the hosts' genomes (Avrani et al. 2011). Similar genetic based resistance may also exist in the expansive diatom genomes (Armbrust et al. 2004; Bowler et al. 2008). Alternatively, predation by viruses may be stimulating phenotypic diversity in diatom communities through Red Queen dynamics where hosts and viruses are constantly evolving in response to each others changing predation or defenses (Van Valen 1973). With some strains being highly susceptible to infection, this pressure may be causing the phenotypic diversification seen in other, closely related strains.

In conclusion, the patterns of virus-*Pseudo-nitzschia* interactions may suggest a paradigm that differs from the role of viruses as terminators of phytoplankton blooms. Instead, diatom blooms are complex communities and diatom diversity, whether stimulated by viral predation or as a result of other resistance factors, may impede viral termination. The host specific interactions can lead to large variability in infectivity and virus titers. Furthermore, these patterns

do not follow host phylogeny as we can measure it with the ITS1 region. Methods that estimate community composition or abundance using these markers do not capture viral infection phenotype, as strains sharing 100% ITS1 identity isolated from the same water yielded different titers and susceptibilities to viral infection. Also, the infection patterns suggested connectivity between the communities of Puget Sound and the Washington coast, with viruses being most infective of their co-occurring hosts. Finally, not only did the diatom hosts display many different infection phenotypes, but the viral communities were also diverse and ephemeral. The taxonomic and temporal scales of diatom-virus interactions uncovered here illustrate the importance of permissivity and host range and emphasize the need to determine the cellular mechanisms of these attributes. Ultimately this will lead to a quantitative understanding of the impacts of viral infection on abundance and structure of wild diatom populations.

Chapter 3

Caught in the act: Infection by wild viruses observed through viral transcription

3.1 Abstract

Viruses are the most abundant and diverse predators in the ocean, and have been hypothesized to structure microbial communities and influence global biogeochemical cycles. Yet viral infection is rarely directly assessed in the environment. We sought to understand viral infection in the ocean by observing the transcription of viruses. Viral metagenomes were paired with size-fractionated cellular metatranscriptomes taken in the North Pacific ocean along Line P. A small fraction of the total virus community was observed to be actively transcribed; 16% at the most coastal station and only 0.2% in the most oceanic station. Viral abundance was compared to host abundance for the well-described virus groups of cyanophage, SAR11 phage, virophage and picoeukaryote viruses. In some cases, high virus:host ratios were observed without high transcription by the viruses, suggestive of a recent lysis event. On the other hand, several virus groups had above average expression, but a low virus:host ratio indicating that they were in the process of overtaking a dominant microbial taxon. Additionally, the infection dynamics of underexplored viral groups, such as archeoviruses and ssDNA viruses, indicated that new uncultured groups of viruses were transcriptionally active and shed light on who those viruses may have been infecting. *Synechococcus* phage were used as a model to understand how the genomic potential of viruses influences their success in the ocean. *Synechococcus* phage similar to three isolates were most abundant, and only 2 strains had significant expression. Suites of auxiliary genes were identified, but only at one station were host-derived photosynthesis genes

significantly expressed. This coincided with a cyanophage community with unusually high transcription intimating that auxiliary genes may provide a competitive advantage to viruses in the ocean. Directly observing viral infection revealed hidden dynamics of wild viral communities and underscored the necessity to understand these processes in order to quantify the contribution of viruses to microbial ecology and biogeochemistry.

3.2 Introduction

Viral infection and lysis in the marine environment have been proposed as major catalysts of biogeochemical cycling and processes which structure microbial communities. Because of the release of cell contents into the water column, viral lysis is estimated to move 150 Gt C y^{-1} from the particulate phase to the dissolved phase, which is an order of magnitude more than any other process contributes to carbon fluxes between environmental reservoirs (Suttle, 2005). However, the underlying estimates of viral infection that contribute to these global scale projections are poorly quantified. Estimates of viral contributions to mortality in microbial populations range from 2% to 100% (Cottrell and Suttle, 1995; Jacquet et al., 2002). The methods used to determine *in situ* infection rates lack adequate sensitivity to detect viral production or have significant biases (Brussaard, 2004). Epifluorescent microscopy, which can be used to count changes in viral abundance does not detect RNA, single stranded, or small viruses and may be missing half the viruses in the ocean (Steward et al. 2012). Since viruses lack a common genetic marker, most molecular tools can only target portions of the viral community.

The advent of metagenomics has allowed culture-independent analysis of entire *in situ* viral assemblages (Breitbart et al., 2002). Early viral metagenomes quickly revealed that viral genetic diversity was immense (Angly et al., 2006; Breitbart et al., 2002; Culley et al., 2006).

Furthermore, investigations targeting viral groups such as microphage, eukaryotic ssDNA viruses, positive sense RNA viruses, and dsDNA viruses have confirmed that viral diversity is high (Hopkins et al. 2014, Labonte et al. 2013, Culley et al 2014, Schmidt et al. 2014). However, viruses appear to be widely dispersed which contributes to lower global diversity (Angly et al. 2006, Breitbart et al. 2004, Brum et al. 2015). The ‘every virus is everywhere’ hypothesis (Breitbart and Rohwer, 2005) suggests that a diverse and cosmopolitan population of viruses serves as a reservoir for infection (Goldsmith et al. 2015). This raises the question of how this reservoir is maintained.

While metagenomics has enabled a more comprehensive view of viral communities, ~90% of viral sequences from metagenomes are novel (Angly et al. 2006, Hurwitz et al. 2013). Additionally, information about viral interactions with their hosts is nearly completely lost when only sequencing the viral fraction. Furthermore, certain viral types, such as single stranded viruses and RNA viruses, are still misrepresented or omitted in viral metagenomes because they require extra steps to convert to dsDNA needed for sequencing (Duhaime et al. 2012). When viromes do target these groups, dsDNA is often synthesized from random amplification, which preferentially targets small circular single stranded templates, and is not quantitative (Yilmaz et al. 2010).

The inability to measure infection in the environment still substantially hinders the field of viral ecology. Metaproteomic and metatranscriptomic approaches have serendipitously shed light on viral dynamics in the field. On a south Atlantic transect, viral proteins were the fourth most abundant peptide identified in bacterial proteomic samples (Morris et al., 2010). Despite the shift in microbial communities along this open ocean to coast transect, the fraction of viral protein spectra was split evenly between the two regimes (Morris et al., 2010). Two

interpretations of this data are viruses are being passively trapped on filters at equivalent concentrations in both regimes or that viral infection is equally prevalent in both environments despite changes in the host communities. Metatranscriptomic approaches paired with metagenomes have provided direct insight into the dynamics of viruses during the course of phytoplankton bloom. In mesocosm experiments, paired metagenomes (targeting the bacterial size fraction) and bacterial metatranscriptomes were taken at the bloom's peak and after the bloom (Gilbert et al., 2008). Post bloom, viral transcripts were 24.5 times higher than bloom peak, dominating the transcriptional signal in that sample (Gilbert et al., 2008). Even with poor identification of viral sequences, this indicates that metatranscriptomics can successfully capture active viral infection in the field.

We sought to understand viral infection in the ocean by observing the transcription of viruses. The Global-scale Microbial Interactions across Chemical Survey (GeoMICS) cruise in May 2012 combined organic and trace metal geochemistry with genomic techniques to survey how microbial processes impact ocean chemistry. The cruise sampled four stations on a transect from the coast of Washington state to the open North Pacific ocean along Line P. These stations traversed chemical gradients and changes in microbial communities. This provided an excellent opportunity to survey the corresponding changes in the viral community and identify and quantify actively infecting viruses. Four viral metagenomes were taken in coordination with cellular metatranscriptomes, providing a holistic view of viral infection.

3.3 Methods

Sample collection

Samples were collected along the Line P transect in the northeastern Pacific on the R/V

Thomas G. Thompson from May 16-21, 2012 as part of the Global-scale Microbial Interactions across Chemical Survey cruise. At four stations, P1 (48.58 N, 125.50 W), P4 (48.65 N, 126.67 W), P6 (48.74 N, 127.67 W) and P8 (48.82 N, 128.66 W), a conductivity temperature depth with 10L niskin bottles was used to collect water from 5m depth. Plankton were collected on a 2.0 μm pore-size filter (142 mm diameter polycarbonate) and a 0.2 μm pore-size filter (142 mm diameter Supor) following prefiltration through a 53 μm pore-size filter. Filters were flash frozen in liquid N_2 and stored at -80°C . 20L of the $<0.2 \mu\text{m}$ filtrate was amended with iron chloride (1g L^{-1}) and incubated for at least 1 hour at room temperature to flocculate viruses (John et al. 2011). Viral flocculates were filtered onto 0.6 μm polycarbonate filters and stored at 4°C .

Virome construction, sequencing, and assembly

Viruses were resuspended from filters by incubating them with 20ml of 0.2M ascorbate-0.25M EDTA-Mg²⁺-0.25M Tris-HCL for 24 hours with periodic shaking (John et al. 2011). Viral suspensions were incubated for 2 hours at room temperature with DNase 1 (100 U ml^{-1} , Ambion) to remove contaminating extracellular DNA. Viral DNA was extracted using a MoBio PowerSoil Total RNA isolation kit with the DNA elution column accessory, according to the manufacturers instructions. To convert single stranded DNA (ssDNA) viruses to double stranded DNA (dsDNA), complementary strands were synthesized using a modified random priming-mediated sequence-independent single-primer amplification (RP-SISPA) method designed to generate quantitative whole genome shotgun libraries (Djikeng et al. 2008, Culley et al. 2010). Triplicate 20 μl reactions for each sample and a no template control containing 10 μl template (or water), 0.2mM dNTPs, 0.5 mM DTT, 1 μM FR26RV-N primer (5'-GCCGGAGCTCTGCAGATATCNNNNNN-3'), 1mM MgCl_2 , and 1X Klenow buffer were

heated to 94 °C for 3 minutes and snap cooled on ice. 2.5 U of Klenow Fragment, 3'-5' exo- (New England Biolands) was added to each reaction then incubated at 37 °C for 60 minutes followed by 75 °C for 10 minutes. Reactions were pooled, cleaned with an ethanol precipitation, and resuspended in T low-E (10mM Tris-HCl, 0.1 mM EDTA pH 8.0).

To construct Illumina shotgun metagenome libraries, viral DNA was sheared to 800-1000 bp using a Covaris nebulizer and cleaned with AmPure XP beads. Viral metagenomes (viromes) were constructed using the Rubicon ThruPLEX-FD Kit, which uses qPCR to linearly amplify low concentration DNA templates. Libraries were sequenced on an Illumina HiSeq 2500 with 150bp paired end reads at the Michigan State University Sequencing Center.

Virome reads were trimmed of adapter sequences and low quality regions and filtered to remove low quality reads with the Trimmomatic pipeline (Bolger et al., 2014). Sequences were *de novo* assembled into contigs by first using diginorm (Brown et al., 2012) followed by the velvet assembler (Zerbino and Birney, 2008) with k-mer length set at 25, 29, 33, 51 for P1, P4, P6, and P8 respectively and a minimum contig length of 200bp. The resulting contigs were cleaned of cellular contamination by first blasting against the RDP database. A custom database of taxa that were identified from the RDP search as well as known gene transfer agent producers was created to search and remove any contigs that were annotated with an e-value of 1e-20 or lower to these contaminants. These putative cellular contigs were then blasted against viral ref seq, and hits of < 1e-100 were blasted against nr and added back to the viromes if the top 5 blast hits were viral, which occurred with <1% of the contigs.

Contig annotation and binning

Contigs were annotated by the best blast hit against viral ref seq (searched on September 16th, 2015) at an e-value cutoff of 1e-5. Host:virus ratios were calculated by dividing normalized viral abundances by normalized 16S tag sequencing abundance (Limnardo and Worden, unpublished data).

Metatranscriptome construction and sequencing

RNA was prepared for sequencing as previously described (Durham et al 2015). Briefly, cells were lysed in 10 mL of Ambion lysis buffer (AM8540G) + 0.5 mL each of 0.5 and 0.1 mm zirconia beads (BioSpec Products, Inc.), and an internal standard 1,006 nt in length (Satinsky et al 2013) was added to the lysis buffer in known copy numbers. Total RNA was treated for DNA contamination using two successive treatments with Turbo-DNase (Ambion; Life Technologies) and cleaned/concentrated with an RNeasy MinElute Cleanup Kit (Qiagen). rRNAs were removed using a subtractive hybridization method (Stewart et al 2010) with biotinylated rRNA probes specific to the environmental samples (i.e. bacterial and archaeal 16S and 23S and eukaryotic 18S and 28S). Probe-bound RNAs were removed with streptavidin-coated magnetic beads (New England Biolabs). Depleted RNA samples were linearly amplified using the MessageAmp II-Bacteria kit (Ambion; Life Technologies).

Amplified mRNAs were converted into cDNAs using the Superscript III First-Strand Synthesis System (Invitrogen; Life Technologies) followed by the NEBNext mRNA Second Strand Synthesis Module (New England Biolabs). cDNAs were then purified using either the PureLink PCR Purification Kit (Life Technologies) or the QIAquick PCR purification kit (Qiagen) followed by ethanol precipitation. cDNAs were sheared ultrasonically to ~250 base pair fragments and libraries were constructed for paired-end (2 x 150) sequencing using either the

Illumina MiSeq or HiSeq 2500 sequencing platform (Illumina Inc., San Diego, CA). Reads were joined using PANDAseq (Masella et al 2012), and paired reads were trimmed using FASTX-Toolkit (http://hannonlab.cshl.edu/fastx_toolkit/). rRNA, tRNA, and internal standard sequences were removed using a BLASTn search against a database containing representative rRNA and tRNA sequences along with the internal standard sequence (bit score cutoff >50).

Metatranscriptome recruitment

BBMap version 35.x was used to map metatranscriptome reads to viral contigs. Contigs were indexed with a padding of 300 and reads with a minimum 98% identity were mapped to contigs. Each contig, therefore, had an RNA coverage and DNA coverage (from assembly), which were used to create a ratio of RNA:DNA for each contig.

Viral phylogenies, read placement, and diversity statistics

Phylogenies of the terminase large subunit (terL), DNA polymerase B (polB), ssDNA replication protein (vRep), major capsid proteins (MCP), and photosystem D1 (psbA) were constructed using RAxML v 8.0 (Stamatakis, 2012). Briefly, reference sequences were downloaded from Genbank and used to search proteins on virome contigs. Together, full or nearly full length virome proteins and reference sequences were aligned with Muscle v 3.8.31 (Edgar, 2004). A maximum likelihood tree was inferred from 20 starting trees using the amino acid substitution model model VTF for terL and polB, PMBF for vRep, VTF for MCP, and MTMAMF for psbA.

Viromes and metatranscriptomes were searched using blast at an e-value cutoff of 1e-10 with representative seed sequences from each of the above genes. Reads were trimmed according

to their blast alignment and aligned to the reference alignment using Parsimony-based Phylogeny-Aware Read Alignment program (PaPaRa) (Berger and Stamatakis, 2011). Reads were then mapped to the reference tree with the Evolutionary Placement Algorithm (EPA) (Berger et al. 2011).

Nodes and leaves from the tree were assumed to be the operational taxonomic units (OTUs). OTUs that did not recruit at least 0.1% of the total placed reads in from either the viromes or metatranscriptomes were removed. Since the terL phylogeny was designed to estimate bacteriophage diversity, bacteriophage OTUs were cut from the polB tree to prevent overrepresentation of bacteriophage taxa. Similarly, non-virophage nodes were removed from the MCP trees. Read abundance was normalized to the average gene lengths of each tree: terL (1000 aa), polB (600), vRep (400), MCP (275). Read abundances were then normalized to library size. OTUs that were ambiguous or unrelated to known groups were designated as unclassified viruses.

3.4 Results

Microbial community composition

Four stations were sampled along Line P in the northeastern Pacific on a transect from coastal waters to the open ocean between May 16-21, 2012 (figure 1a). Satellite derived chlorophyll concentrations for the month of May showed that the coastal station P1 had the highest chlorophyll concentrations, which decreased with distance from the coast at stations P4, P6, and P8. At the time of sampling, diatom abundance was highest at P1 where a bloom of *Pseudo-nitzschia pungens* dominated the community. Diatom abundance based on cell counts was lowest at P6 (Sara Bender, unpublished data, personal communication). Photosynthetic

picoeukaryotes were also most abundant at P1, and decreased at more oceanic stations. However, picophytoplankton became the dominant eukaryotic phytoplankton at stations P4, P6, and P8 (Francois Ribalet, unpublished flow cytometry data, personal communication). Cyanobacteria abundance followed an opposite trend from eukaryotic phytoplankton, being most abundant at the more oceanic station P6 and lowest in abundance at coastal P1 (Francois Ribalet, unpublished flow cytometry data, personal communication). *Synechococcus* clades I and IV composed >95% of the cyanobacterial communities at every station, and clade I was approximately 3 times more abundant than clade IV (Limnardo and Worden, unpublished 16S tag sequencing data).

Viral community composition and diversity

At each of the four stations, cellular metatranscriptomes from particle associated and free-living plankton communities were paired with semi-quantitative viral metagenomes (viromes) taken from the same water sample (figure 1b). Phylogenies of viral hallmark genes were used to assess viral diversity and abundance: the terminase large subunit (terL) represented bacteriophage, DNA polymerase B (polB) represented Nucleocytoplasmic Large DNA Viruses (NCLDV), archeoviruses, and two single stranded DNA (ssDNA) viruses, the major capsid protein (MCP) represented virophage, and the replication associated protein (vRep) represented ssDNA viruses. Sequences from contigs assembled from each station's virome were added to the trees to further capture viral diversity (supplemental figure 1). The leaves and nodes of the four phylogenies were designated as viral operational taxonomic units (OTUs) and 281 out of 972 possible OTUs recruited reads from the viral metagenomes or cellular metatranscriptomes. In the

viromes, 175 of the 281 OTUs were detected at all four stations. In the cellular metatranscriptomes, on the other hand, only 4 viral OTUs were detected at all four stations.

Viral abundance in the viromes did not correlate with high levels of transcription detected in the cellular metatranscriptomes. For example, SAR116 phage were the most abundant viruses at an average of 18.4% ($\pm 8.4\%$) of the total viral community (figure 2), yet represented only 1.2% of the total viral RNA transcripts compared to cyanophage (57.8% of transcripts), pelagiphage (6.6%), and unclassified phage (42.1%). Single stranded DNA (ssDNA) viruses were as abundant as bacteriophage composing 31.1% ($\pm 5.5\%$) of the community, but was the least expressed group of viruses representing only 2.8% of viral transcripts. They could be divided into 10 different groups based on their phylogeny. Each group was detected at every station in the viromes, but they were detected 41% of the time in the transcriptomes. The most detected was uncultured marine viruses at 7 or 8 transcriptomes while the least detected group was diatom viruses, which were never expressed. Viruses with polB including the NCLDV, archaeoviruses, and polB encoding ssDNA viruses were only 3.9% of the viral community, yet were comparable in their expression to ssDNA viruses and bacteriophage. Of that group, the photosynthetic picoeukaryote infecting phycodnaviruses were both the most abundant and the most expressed. Finally, virophage were both highly abundant and highly expressed, accounting for 28.1% ($\pm 9.0\%$) of the viral community and 77.6% ($\pm 14.6\%$) of the viral expression.

Connecting viral infection to host dynamics

Host abundance, viral abundance, and viral expression were examined for viral groups for which hosts have been identified in the marine environment. These host-viral groups are the *Synechococcus* and *Synechococcus* phage (Millard et al., 2009), *Pelagibacter* and pelagiphage

(Zhao et al., 2013), photosynthetic picoeukaryotes and picoeukaryote viruses (Nagasaki 2008), and Nucleocytoplasmic Large DNA viruses (NCLDVs) and virophage (Zhou et al., 2013). Additionally, diatoms were compared to eukaryotic single stranded DNA viruses, since diatoms are the only known hosts in the marine environment (Kimura and Tomaru, 2015), even though many of the eukaryotic ssDNA vRep sequences were not located within the known diatom virus clade (supplemental figure 1c). Virus to host ratios for cyanophage and picoeukaryote viruses were highest at P6, while pelagiphage, ssDNA viruses, and virophage had the greatest virus to host ratio at stations P1, P4, and P8 respectively (figure 3). Virus host ratios varied an order of magnitude or greater within each group at different stations (figure 3). The expression of each viral group varied by station. Cyanophage at P4 and pelagiphage at P1 had high virus:host ratios, but below average expression. However, most viral communities had low host:virus ratios but had higher than average expression. There were few instances where high virus:host ratios corresponded to high transcription, specifically P6 ssDNA viruses and P4 picoeukaryote viruses. For both of these instances, host abundance was the lowest observed across the entire transect. In fact, a negative logarithmic correlation existed between virus:host ratios and host abundance for all groups and stations (linear regression $R^2=0.66$, $p=0.0001$).

Strain specific expression differences

Viromes were assembled into contigs; over half of the reads from P4 and P6 viromes assembled, while 20% and 27% of P1 and P8 reads assembled respectively (supplemental table 1). A small minority of contigs from each virome recruited reads from the cellular free-living and particle attached metatranscriptomes (supplemental figure 2). The expressed fraction of the viral community decreased from the coastal station, at P1 with 16% of viral contigs expressed, to the

oceanic station, at P8 with 0.2% of contigs expressed. Viral contigs from each station recruited on average 0.48% ($\pm 0.16\%$) of reads from the corresponding free-living metatranscriptome versus 0.77% ($\pm 0.25\%$) of reads from the corresponding particle-attached metatranscriptome.

The viral groups examined above at P6 appeared to have consistently higher expression compared to other stations (figure 3). Examining expression of individual contigs revealed that P6 had a small group of contigs that were expressed orders of magnitude more than any other contig at the other stations (figure 4). *Synechococcus* phage, picoeukaryote viruses, and poxviruses were members of that highly expressed group (supplemental table 2). Most of these highly expressed contigs contained genes of hypothetical or unknown function. A putative structural protein and auxiliary metabolic gene (2OG-Fe(II) oxygenase) were identified on two of the cyanophage contigs and a putative ATP-binding cassette transporter containing contig from a poxvirus were highly expressed in both fractions (supplemental table 2).

Synechococcus phages were used as a model to explore strain specific differences in expression. A phylogeny of large terminase (*terL*) genes was constructed specifically to finely resolve taxonomic differences in *Synechococcus* phages using sequences from 34 complete *Synechococcus* phage genomes and other bacteriophage (supplemental figure 1a). Virome reads were mapped to the reference tree to identify and quantify *Synechococcus* phage at each station. Reads mapped to 29 of 34 isolates, and three isolates, S-RIP1, P60, and S-CRM01, recruited the 57% of reads (figure 5a). Furthermore, S-RIP1 and P60 represented 71% of the total *Synechococcus* phage transcripts. While both isolates recruited similar numbers of *terL* transcripts from stations P1, P4, and P6, at station P8 the P60 isolate recruited significantly more transcript reads.

Synechococcus phages are known to have different suites of host-derived auxiliary metabolic genes that are expressed during infection and that may benefit the viruses during replication (Labrie et al. 2013, Lindell et al. 2007, Bragg et al. 2009). Cyanophage auxiliary metabolic genes were detected in viromes at every station (figure 5b, supplemental table 2). Carbon and nucleotide metabolism, photosynthesis, and phosphate uptake related genes were the most abundant auxiliary metabolism genes at each station and occurred in similar ratios, except at station P1 (figure 5b). *PsbA* sequences, which encode the photosystem II D1 protein, in the viromes were phylogenetically related to previously sequenced cyanophage indicating that the photosynthesis genes were virally encoded (supplemental figure 3). However, the expression of these genes was dramatically different (figure 5c). Despite, P4 and P6 having nearly identical auxiliary metabolic gene abundances (figure 5b), photosynthesis genes were significantly more expressed at station P6 (figure 5c). In contrast, at station P4, an integrase, rather than a host-derived metabolism gene, was the most expressed auxiliary gene. At P6, 3 contigs out of 75 that were two standard deviations above the mean expression were photosynthesis related. These included a 2OG-Fe(II) oxygenase and photosystem II D1 protein (*psbA*), which were the 15th and 34th most expressed contigs in the free-living community, respectively, and a photosystem II D1 protein that was the 15th most expressed contig in the particle attached community. Interestingly, also in the top most expressed genes at P6 was a putative *ftsH2* gene from a picoeukaryote virus, which may help with the repair of photosystem D2 proteins (Komenda et al. 2010, Zaltsman et al. 2005).

3.5 Discussion

In 2007, Suttle suggested that viruses employ different life history strategies based on their replication dynamics and the population dynamics of their hosts to survive in the ocean. Viruses that have high burst sizes and replicate rapidly to take advantage of ephemeral host populations would be *r*-selected, while viruses that produce small numbers of progeny viruses upon lysis and co-exist with more stable host populations would be *K*-selected. This framework was based on culture-based observations of viral dynamics, but has not been evaluated in the environment. The changes in community composition of actively infecting viruses provided a window into the lifestyles of the viral taxa at these four stations. A small fraction of the viral community is actively infecting. This suggests that a few viral taxa out of the larger viral reservoir were proliferating. Several poorly understood viral taxa were caught in the act of infection.

Eukaryotic ssDNA viruses were abundant yet were the least transcriptionally active viral community at every station. Currently, diatoms are the only known hosts of eukaryotic ssDNA viruses in the marine environment (Kimura and Tomaru 2015). Curiously, despite the bloom of the diatom *Pseudo-nitzschia pungens* at P1, only 2 of 57 viral replication associated protein sequences from ssDNA viruses grouped with previously sequenced diatom viruses. This suggests that there may be considerably more diversity than the previously isolated diatom viruses. In fact, many of those sequences grouped with parvoviruses, which are linear ssDNA viruses, or an uncultured clade of ssDNA viruses, both of which have no known hosts, suggesting there may be other groups of ssDNA viruses that infect diatoms in addition to the currently isolated group or other hosts for ssDNA viruses in the marine environment besides diatoms. Diatom-infecting ssDNA viruses have been documented to have burst sizes in the range of thousands to tens-of-thousands per cell (Kimura and Tomaru, 2015). It appears that they may be examples of *r*-

selected organisms with high burst sizes that replicate rapidly to take advantage of ephemeral host populations.

In contrast, the other group of eukaryote infecting viruses which infect photosynthetic picoeukaryotes and heterotrophic unicellular protists, the NCLDV were proposed as *K*-selected viruses (Suttle, 2007) because they have lower burst sizes and their host populations are more stable. They were less abundant than the eukaryotic ssDNA viruses, but were more expressed than ssDNA viruses, suggesting that they employ a different strategy than the ssDNA viruses.

Virophage infect other viruses belonging to the NCLDV (LaScola et al. 2008). The environmental sequences from the viromes were not closely related to any of the isolated virophage, but instead related to virophage sequences from animal gut and freshwater metagenomes (Yau et al., 2011, Yutin et al., 2015). Using the hallmark genes to recruit virome and transcriptome reads revealed that they were among the most abundant viruses observed and accounted for the majority of viral transcription. Thus virophage are likely significant top down controls on NCLDV populations in the environment.

Archeovirus dynamics are poorly understood in the ocean. To date, archeoviruses have only been identified in marine sediments (Paul et al. 2014) and not in the water column. Two polymerase B sequences from these pelagic viromes were most closely related to extremophilic euryarchaeal viruses. Additionally, Marine Group II euryarchaea were the most abundant archaeal taxa in the cellular community (data not shown). Thus, these viruses may be infecting Marine Group II archaea. The archeoviruses were detected in every virome, and transcriptionally active at all the stations except P8. The recent genome sequence and community analysis of a coastal metagenome revealed that marine group II euryarchaea are important components of microbial

communities, are motile, and may be associated with diatoms or large phytoplankton (Iverson et al. 2012), which were scarce at P8.

Viruses are architects of microbial community structure

Viral infection has been proposed as an important process, which structures microbial community composition and abundance. However, bottom up controls on microbial communities are excellent predictors of community structure independent of estimations of virally induced mortality (Follows et al., 2007). Host abundance, viral abundance, and viral transcription combined to reveal microbial communities engaged in different viral dynamics. The ratio of viruses to hosts varied up to 2 orders of magnitude between stations within a virus-host groups. Hypothetically, a high virus:host ratio is evidence of lysis, which reduces host numbers and increases viral abundance. High virus:host ratios were correlated with low host abundance. However, a high virus:host ratio did not necessarily coincide with high transcriptional activity of the viruses. The highest virus:host ratios for pelagiphage and cyanophage at P1 and P4, respectively, were linked to lower than average viral transcription. Few virus-host groups had both high expression and high virus:host ratios. Viruses with both high expression and high virus:host ratios may have been caught in the act of infecting a host population. In fact, many more viral populations had higher than average transcription, but low virus:host ratios. This is suggestive of impending lysis. These viral populations with different virus:host ratios and transcription are reminiscent of kill-the-winner dynamics, where relatively few viral taxa are actively infecting the most prolific hosts, which are then supplanted by new microbes (Thingstad et al. 2000). The lens of transcription highlights those viral taxa that are the current ‘winners’, those viruses that were once winners, and the bank of viruses that may succeed the current

winners. This provides a mechanistic link between kill-the-winner dynamics (Thingstad et al. 2000) and the viral seed bank hypothesis (Breitbart and Rohwer, 2005).

Auxiliary genes and the success of viruses

Kill the winner dynamics are thought to occur at the strain, rather than population level (Thingstad et al. 2015). While population level changes in host abundance were correlated with virus:host ratios, the taxonomic binning based on blast annotation did not provide enough resolution to determine if single strains of viruses were driving the overall transcriptional changes or if the entire viral population was just more infective. The transcription of individual contigs showed that P6 had a handful of contigs that were the highest expressed in the entire study. Picoeukaryote viruses, poxviruses, and cyanophage were the main members of that group. Intriguingly, these same groups at P6 had low or average virus:host ratios suggesting that these highly expressed viruses may have been in the process of removing a ‘winning’ host population. The importance of differences between strains and the effect those differences has on the success of viruses in the ocean is poorly understood.

Culture dependent work with cyanophage has shown important differences that occur at the strain level. Even though phage usually infect a narrow range of hosts, there are single hosts that are able to be infected by multiple phages (Dekel-bird et al 2014) and certain phages are able to infect multiple hosts (Sullivan et al. 2004, Flores et al. 2011). Therefore, cyanophages are likely competing with each other for hosts in the environment. Interestingly, in addition to lineage-defining viral genes, cyanophage genomes frequently encode host-derived and other auxiliary genes (Sullivan et al. 2005). These genes are involved in the hosts’ metabolism, specifically in photosynthesis, light stress, phosphorous acquisition, and carbon metabolism

(Labrie et al. 2013). Viruses express these host-related genes during infection (Lindell et al. 2005, Lindell et al. 2007). Modeling studies suggest that host genes may allow the viruses to ultimately produce more progeny viruses under certain conditions (Bragg et al. 2008, Hellweger 2009). Not all cyanophage encode host metabolism genes or have the same suite of genes (Labrie et al. 2013, Dekel-bird et al. 2014). Therefore, we explored whether there were expression differences by strain and whether host metabolism genes might have played a role in the success of *Synechococcus* phage at the four stations.

Using a phylogenetically enabled approach showed that *Synechococcus* phage communities were composed of viruses similar to 29 different isolates, with viruses similar to 3 isolates dominating the community at every station except P1. Two of those three most abundant strains were highly expressed. One of those isolates, P60, does not have photosynthesis genes (Chen and Lu 2002) while the other, RIP-1, encodes the photosynthesis gene *psbA*. Cyanophage at P1 had a different ratio of auxiliary genes compared to the other stations, possibly explained by the differences in the phage community. P4 and P6 were remarkably similar in auxiliary gene abundance, virus abundance, and host community composition (Limnardo and Worden, unpublished data). Strikingly, however, photosynthesis genes had significantly higher expression at P6 and were, in fact, some of the highest expressed genes in the whole viral community. Integration genes were the most highly expressed at P4, on the other hand. These two communities lie on different quadrants of the virus:host ratio vs expression plot. The P4 community has a high virus:host ratio, but lower than average expression indicating that viruses in the community may have recently lysed a dominant *Synechococcus* strain. When host abundance is low, viruses may integrate in order allow them to continue to persist in the environment (McDaniel et al. 2002). On the other hand, P6 communities seem poised to

dethrone the current winning host taxa. Their expression of photosynthesis genes may have facilitated their success over non-photosynthesis containing phage. Additionally, the expression of these host genes is a window onto the stressors of the host (Lindell et al. 2007). A putative *ftsH2*, which is involved in photosynthesis and photosystem II repair *Synechocystis* and *Arabidopsis* (Komenda et al. 2010, Zaltsman et al. 2005) was also one of the highest expressed genes at P6, but was encoded by a picoeukaryote virus suggesting that other groups of viruses may be utilizing similar pathways to manipulate host metabolisms in similar environments. Therefore, these auxiliary host genes are likely important tools that viruses leverage for situational success in the marine environment.

Ultimately, any virus that is infecting a host and presumably making progeny viruses is successful as they have survived numerous obstacles such as diffusion, finding a host, and conquering host immunity. Pairing metatranscriptomes with metagenomes has provided a new insight onto essential questions about which viruses are successful and why they might be succeeding. This technique uncovered a link between two major conceptual models of viral ecology, viral seed bank and kill-the-winner dynamics. Directly quantifying viral infection is a critical and significant step towards understanding how viruses contribute to microbial community composition and biogeochemical cycling.

3.6 Acknowledgements

We would like to thank the captain and crew of the RV R/V *Thomas G. Thompson* as well as co-chief scientist of the GeoMICS cruise, Jim Moffett. Additionally, we would like to thank all the members GeoMICS working group and in particular, Sara Bender and Megan

Schatz for diatom counts, AJ Limnardo, Alex Worden for 16S tag sequencing data, Francois Ribalet for underway plankton data, and Jaci Saunders for obtaining the samples. Also, we are appreciative of the assistance of Clara Fuchsman and Cedar McKay in virome assembly.

Funding was provided by a grant from the National Science Foundation: OCE-1356779 to GR and a University of Washington, School of Oceanography Innovation Grant to MC. MC was funded by an EPA STAR fellowship.

3.8 Figure legends

Figure 3.1 Sampling of metatranscriptomes and viromes along the Line P transect. a) Satellite derived chlorophyll concentrations for May 2012 and the locations of the 4 stations where metatranscriptomes and viromes were taken. b) Schematic of water sampling at each station showing fractionation of the same water used to create free-living and particle attached metatranscriptomes and viromes.

Figure 3.2 The abundance and expression of viral groups from each station. Reads from viromes and metatranscriptomes were identified and quantified by mapping to four phylogenetic trees of DNA polymerase B, major capsid protein, replication associated protein, and the terminase. Viral abundance is expressed as logarithm of read abundance after normalization for gene size and library size. Warm colors represent higher viral abundance or transcription while cool colors represent lower abundance or transcription. Black indicates no viruses were detected.

Figure 3.3 Comparison of virus:host ratio to viral expression. The x-axis is the virus host ratio plotted on a log scale. The y-axis is the log ratio of RNA coverage to DNA coverage centered at the average ratio for all expressed contigs. The shaded region represents the standard deviation around the mean expression. Viral groups with known hosts in the marine environment (colors) are plotted by station (shapes): red is diatoms and ssDNA viruses, yellow is photosynthetic picoeukaryotes and their viruses, dark blue is *Synechococcus* and their phage, cyan is SAR 11 and pelagiphage, green is NCLDVs and virophage. Circles are station 1, diamonds are station P4,

squares are station P6, and triangles are station P8. No expression was detected for P1 virophage represented by an unfilled circle at the lowest possible expression.

Figure 3.4 Per contig expression for expressed contigs at each station: a) P1 b) P4 c) P6 d) P8. Expression above 0 means contigs recruited more RNA reads than DNA reads. Circles are contigs expressed in the free-living fraction, triangles in the particle attached. Lines represent two standard deviations above the average expression for that station. Teal is for free-living expressed contigs, orange for particle associated.

Figure 3.5 Strain specific *Synechococcus* phage abundance and expression. a) Abundance (top) and expression (bottom) of *Synechococcus* phage strains based on phylogenetic placement of virome and metatranscriptome reads. b) Abundance of cyanophage auxiliary genes in viromes grouped by function at each station. c) Expression of cyanophage auxiliary genes with the standard deviation for each group. Error bars are standard deviation

Conclusion

Viral ecology has blossomed in the genomic era, which has enabled unprecedented depth and breadth of insight into viral dynamics. By far, the overwhelming headline has been how incredibly diverse viruses are (Brum et al. 2015). In every environment (Angly et al. 2006, Aguirre de Carcer et al. 2014, Yoshida et al. 2013, Cassman et al. 2012) and for every type of virus (Hopkins et al. 2014, Labonte et al. 2013, Culley et al. 2014, Schmidt et al. 2014), previously unknown, uncultured viral groups are being discovered. Certainly, this theme of novel diversity is highlighted in this thesis. In chapter one, the *Pseudo-nitzschia multiseriis* DNA virus (PmDNAV) expanded the current boundaries of single stranded DNA viruses (ssDNA) having the largest ssDNA genome and a novel polymerase not typically seen in ssDNA viruses. Chapter 2 reveals even diatom hosts have surprising microdiversity in their susceptibility to infection to the PmDNAV and whole viral communities. Finally, the viral communities on the GeoMICS transect in chapter 3 also followed the theme of diversity with ~70% of sequences not similar to previously sequenced viruses. Summarily, this diversity can be overwhelming and lends itself to the conclusion that there will never be enough viruses isolated or viral communities sequenced to capture the diversity of viruses in the ocean.

Despite this diversity, viruses are united functionally through infection. Focusing on this process, which requires understanding infection from both the host's and the virus's perspective begins to simplify this diversity and reveal emergent patterns in viral ecology. However, understanding infection at the microbial is not trivial because microbes do not have easily identifiable symptoms. Working with model systems empowers our ability to understand environmental dynamics. This thesis attempted to create this bridge, focusing on diatoms as model system and exposed three overarching themes.

First, viruses are not just specialists for one host (Brussaard et al. 2004), but instead viruses lie on a spectrum of specialists to generalists and that spectrum influences their ecology. The isolation of the broad host range PmDNAV shattered the paradigm that diatom viruses, which had mostly only been isolated on one genus of diatom, *Chaetoceros*, are only specialists. Furthermore, diatoms of the genus *Pseudo-nitzschia* clearly ranged in their permissivity to viral infection. This permissivity may even be a significant factor influencing infection dynamics. This nested pattern of host-virus interactions affects the bloom and crash cycles of diatom populations. There is mounting evidence that diatom blooms, even monospecific ones, are composed of a diversity of hosts (Rynearson et al., 2005, Alexander et al. 2015). Varying susceptibility to viruses within a diatom bloom may be a defense against viral termination at a time when viruses would thrive. Viruses, including the PmDNAV, try to take advantage of these situations. They replicate quickly and have huge burst sizes. During times of host scarcity, the host dependent differential infection dynamics observed in the PmDNAV suggests that viruses may cobble together an existence with different infection dynamics until the next bloom arrives. Ultimately, perhaps there is trade-off between viruses with different types of host ranges, with specialists possibly dominating times of high productivity, but generalists being steadier in their abundance throughout the seasons.

Second, key viral genes may be as important for viral success as their host range. Host ranges and host permissivity are determined by specialized, hypervariable regions in both host and virus genomes (Weitz et al. 2012, Avrani et al. 2011). However, other genes, like the auxiliary metabolic genes in cyanophage or varying types of polymerases may be as essential for viral dynamics. In cyanophage, these genes are likely responsible for altering the infection process, changing latent periods and burst sizes (Lindell et al. 2005, Lindell et al., 2007). The

difference in mutation rates between rolling circle replication proteins and DNA polymerases such as that which was found in the PmDNAV, may influence genome size and generally affects the evolutionary trajectory of a virus (Duffy et al. 2008). Indeed, these non-host derived auxiliary genes that affect infection dynamics such polymerase processivity or error rates (Tabor et al., 2007, Banach-Orlowska et al. 2005) may be as important as the unique virally encoded host genes in defining a virus' niche.

Finally, viral population diversity and host community structure are linked through 'kill-the-winner' dynamics. The patterns of occurrence and resistance observed in chapter two hinted at the existence of this diversity sustaining and population structuring mechanism. Only when directly observing infection in chapter three could these dynamics be more clearly seen. Despite the strain level variation in hosts and viruses, viruses may still affect population wide community structure and abundance. Furthermore, instead of microbial populations changing in response to bottom up effects, chapter three suggested viruses may work in tandem with environmental gradients to shape microbial abundance.

In conclusion, viruses are more than just predators of marine microbes. They are diverse and abundant architects of microbial communities, affecting all life, at all scales. Viruses have adopted a variety of lifestyles to be successful in a diffusive patchy ocean. Ultimately, viral infection is an essential cog that connects the gears of marine microbial ecology and global biogeochemical cycles.

Appendix I

Infection dynamics of the *Pseudo-nitzschia multiseriis* DNA virus

A one step growth curve was performed on the original isolating host, *P. multiseriis* CLnn-16 (figure 1), using the methods outlined in chapter 1. The cultures used in this growth curve were not axenic, unlike the *P. multiseriis* PC9 and *T. pseudonana* CCMP1335 cultures described in chapter 1. *P. multiseriis* CLnn-16 cultures were grown at 0.25 day^{-1} under the same conditions as in chapter 1. Significant changes in the CLnn-16 host cells were noticeable as early as 4 hours post inoculation when declines in host abundance was apparent (figure 1a). The latent period was 12-16 hours post infection, and the burst size was $9,300 \text{ viruses cell}^{-1}$ (figure 1b). Bacteria doubled in abundance over the course of the one step growth curve (figure 1c).

Photosynthetic changes were observed in host cells in all three one step growth curves (performed on *P. multiseriis* CLnn-16, *P. multiseriis* PC9, and *T. pseudonana* CCMP 1335). Chlorophyll-a fluorescence was measured using a Turner AU-10 fluorometer at every time point in all three experiments. Photosynthetic yield of photosystem II (Fv/Fm) was measured with a PhytoPAM fluorometer (Waltz) in the *T. pseudonana* experiment. Declines in the chlorophyll-a concentrations began at 4, 32, and 48 hours post infection in *P. multiseriis* CLnn-16, *P. multiseriis* PC9, and *T. pseudonana* CCMP 1335 (figure 2). This coincided with declines observed in host cell number. Chlorophyll-a fluorescence never reached a value of 0 suggesting that chlorophyll remained in the medium to be detected after the cells had died. Photosynthetic efficiency also declined in concert with chlorophyll-a fluorescence at hour 48 in the *T. pseudonana* one step growth curve (figure 2c). Changes in host cells during infection, primarily shrunken chloroplasts and a change in color from brown to green, were noticeable via light

microscopy (figure 3a). Although cells were lysed which was apparent in the lack of a nucleus compared to control cultures (figure 3b and c), only a few cells were noted to be broken.

Finally, the infectivity of the PmDNAV was assessed under different conditions. The PmDNAV stocks were heated or chilled for 15 minutes at -80, -20, 4, 29, 50, and 100 °C. The viral solutions were allowed to return to room temperature and then inoculated into cultures. For UV treatment, virus aliquots were exposed to a UV lamp (American Ultraviolet Company) with 800 μm^2 at 30.5cm distance for 1, 10, and 60 minutes. In each treatment, cultures of *P. multiseriis* CLnn-16 were counted, inoculated with treated PmDNAV stocks to equal 13 viruses per cell, and monitored via chlorophyll-a fluorescence. The virus was inactivated by heating to >50°C, while it retained infectivity after 15 minutes of exposure to temperatures from -80°C to 29°C (table 1). Irradiation with UV light inhibited infection of 4 of 5 replicates after 10 minutes, and infection was completely inhibited after 60 minutes of irradiation. No inhibition of infection was seen after 1 minute of UV treatment. Finally, cultures of CLnn-16 showed no difference in susceptibility when inoculated when growing exponentially or 3 days after the onset of stationary phase.

Figure legends

Figure A1. One step growth curve of *P. multiseriis* CLnn-16 infected with the *Pseudo-nitzschia multiseriis* DNA virus. Solid lines represent control cultures while dashed line represent virus infected cultures. Error bars represent standard error of the mean (n=3).

Figure A2. Photosynthetic changes over the PmDNAV infection cycle for hosts *P. multiseriis* CLnn-16 (a), axenic *P. multiseriis* PC9 (b), and axenic *T. pseudonana* CCMP1335 (c). Squares

indicate relative fluorescence values; circles Fv/Fm. Dashed line indicates infected cultures; solid lines indicate controls. Error bars are standard deviation (n=3).

Figure A3. Visual changes in cell characteristics during infection. a) *P. multiseri* CLnn-16 cultures that were treated and lysed with the PmDNAV 24 hours post infection. On the left, a control culture showing healthy brown pigmentation. On the right, an infected culture showing the transition to a green hue. Epifluorescent images of uninfected (b) and infected and lysed (c) *P. multiseri* CLnn-16 cells stained with SYBR Gold viewed at 1000x magnification. Healthy cells show clear nuclei. Lysed cells have no nuclei, but remain intact. Virus like particles can be seen inside the cell.

Tables

Table A1. Effects of temperature, UV, and growth phase on the infectivity of the PmDNAV.

Treatment	Infective
-80 °C	yes
-20 °C	yes
4 °C	yes
29 °C	yes
50 °C	no
100 °C	no
1 min UV irradiation	yes
10 min UV irradiation	partial
60 min UV irradiation	no
Exponential phase	yes
Stationary phase	yes

Curriculum Vitae

Michael Curtis Grier Carlson
University of Washington, School of Oceanography
Box 357940, Seattle, WA 98195-7940
Office: Benjamin Hall 323 Phone : (626) 825-2929

EDUCATION

- 2015 Ph.D., Biological Oceanography
University of Washington, School of Oceanography
Title: The lifestyles of viruses in the sunlit ocean revealed through isolation, genomics, and infection dynamics
Advisor: Gabrielle Rocap
- 2011 M.Sc., Biological Oceanography
University of Washington, School of Oceanography
Title: Isolation and characterization of a virus infecting the toxigenic diatom *Pseudo-nitzschia multiseriis*
Advisor: Gabrielle Rocap
- 2008 B.A., Biology and History
Pomona College

RESEARCH EXPERIENCE

- Present* Postdoctoral scholar
Technion University
Advisor: Debbie Lindell
- 2008-2015 Research Assistant
University of Washington, School of Oceanography
Advisor: Gabrielle Rocap
- 2007-2008 Research Volunteer
San Diego State University
Prevalence of coral- and seawater-associated adenoviruses in impacted coral reefs
Supervisor: Rebecca Vega Thurber
- 2007 Edwin W. Pauley Summer Research Program Participant
Hawaii Institute of Marine Biology, University of Hawaii
Impact of viruses on coral health
Mentors: Ruth Gates and Rebecca Vega Thurber

AWARDS

- 2015 Early Career Award- Life of Diatoms Conference
2013-2014 University of Washington School of Oceanography Research Innovation Grant
2012-2015 Environmental Protection Agency STAR Fellowship
2010-2011 Pacific Northwest Center for Human Health and Ocean Studies Traineeship
2008-2010 Pacific Northwest Center for Human Health and Ocean Studies Traineeship
2007 Edwin W. Pauley Summer Research Program fellow
2007 Hart Institute for American History Research Grant

TEACHING EXPERIENCE

Teaching Assistant:

- Spring 2012 Oceanography 444: Advanced Field Oceanography
Winter 2012 Oceanography 443: Design of Oceanographic Field Experiments
Spring 2011 Oceanography 201: Introduction to Oceanography Lab
Spring 2010 Oceanography 200: Introduction to Oceanography
2010-2014 Guest Lecturer for Oceanography 535 and Oceanography 497

Student Mentoring:

- 2014-2015 Andrea Odell, Profiling single stranded DNA viruses in the North Pacific
2014-2015 David Garcia-Prieto, Metagenomic quantification of cyanophage in oxygen minimum zones
2012-2015 Terence Leach, Resolving the phylogeny of the *Pseudo-nitzschia* genus
2011-2014 Nicolette McCary, Seasonality and host range *Pseudo-nitzschia* and their viruses
2012 Matthew Knight, Biogeography of pathogenic bacteria in the coastal waters of southern California and Mexico
2012 Annie Thomson, Distribution of ammonia-oxidizing bacteria in the eastern tropical North Pacific
2012 Sara Geurtsen, Distribution of denitrifying bacteria in the eastern tropical North Pacific
2009-2011 Kyle Frischkorn, Isolation and characterization of *Pseudo-nitzschia* viruses

PRESENTATIONS

Carlson, M., McCary, N., Frischkorn, K., Leach, T., Rocap, G. Viral control of *Pseudo-nitzschia* communities is driven by host specific interactions. Oral presentation at the Life of Diatoms Conference. July 2015. Seattle, WA.

Carlson, M., McCary, N., Rocap, G. Viral host range and permissivity of the diatom *Pseudo-nitzschia*. March 2015. Oral presentation at Polony Workshop. Haifa, Israel.

Carlson, M., McCary, N., Rocap, G. Viral host range and permissivity of the diatom *Pseudo-nitzschia*. February 2015. Oral presentation at Aquatic Sciences Meeting. Granada, Spain.

Carlson, M., McCary, N., Rocap, G. Viral host range and permissivity of the diatom *Pseudo-nitzschia*. June 2014. Poster at Marine Microbes Gordon Research Conference. Boston, MA.

Carlson, M., McCary, N., Rocap, G. Host range of seasonality of *Pseudo-nitzschia* viruses. February 2014. Oral presentation at Ocean Sciences Meeting. Honolulu, HI.

Carlson, M., Frischkorn, K., Rocap, G. Isolation and characterization of viruses infecting *Pseudo-nitzschia*. January 2013. Poster at Environmental Virology Workshop. Tucson, AZ.

Carlson, M., Guannel, M., Hubbard, K., Port, J., Turner, J. Connecting researchers in oceans and human health (OHH): the OHHI traineeship program of the Pacific Northwest Consortium. October 2010. Poster at Oceans and Human Health Initiative 2010 National Advisory Panel Meeting. Washington, D.C.

Carlson, M., Frischkorn, K., Rocap, G. Isolation and characterization of viruses infecting *Pseudo-nitzschia*. June 2010. Poster at Oceans and Human Health Gordon Research Conference. Biddeford, ME.

Carlson, M. and Rocap, G. Isolation and characterization of viruses infecting *Pseudo-nitzschia*. January 2010. Oral presentation at the UW Oceans and Human Health Seminar Series. Seattle, WA.

Carlson, M. and Rocap, G. Isolation and characterization of viruses infecting *Pseudo-nitzschia*. December 2009. Oral presentation at the University of Washington for the Department of Oceanography. Seattle, WA.

Carlson M., Van Biber, B., Rocap, G. Isolation and characterization of viruses infecting *Pseudo-nitzschia*. November 2009. Poster at 4th Harmful Algae Symposium. Ocean Shores, WA.

Carlson M., Van Biber, B., Rocap, G. Isolation and characterization of viruses infecting *Pseudo-nitzschia*. October 2009. Oral presentation at Oceans and Human Health Initiative Principal Investigators Meeting. Seattle, WA.

Carlson, M. A Pomona perspective on the Edwin W. Pauley Program. July 2009. Invited oral presentation at the 25th Anniversary of the Edwin W. Pauley Program. Kane'ohe, Hawaii.

Carlson, M., Van Biber, B., Rocap, G. Viral-phytoplankton interactions: Isolation, characterization, and ecology of viruses infecting the diatom *Pseudo-nitzschia*. May 2009. Poster presented at the 8th SCOR Marine Virus Working Group Meeting. Newark, DE.

PRESENTATIONS BY UNDERGRADUATE MENTEES

Leach, T., Carlson, M., Guannel, M., Rocap, G. Uncovering the evolutionary history of *Pseudo-nitzschia*. Poster presentation at the Life of Diatoms Conference. July 2015. Seattle, WA.

McCary, N., Carlson, M., Rocap, G. Seasonal and strain specific variation in *Pseudo-nitzschia* virus susceptibility in the Pacific Northwest. Oral presentation at Joint Aquatic Sciences Meeting. June 2014. Portland, OR.

Leach, T., Guannel, M., Carlson, M., Rocap, G. Uncovering the evolutionary history of *Pseudo-nitzschia*. Oral presentation at Ocean Sciences Meeting. Oral presentation at Ocean Sciences Meeting. February 2014. Honolulu, HI.

Frischkorn, K., Carlson, M., Rocap, G. Characterization of viruses that infect *Pseudo-nitzschia*. Oral presentation at Oceans and Human Health Seminar. November 2010. Seattle, WA.

CRUISES AND FIELD WORK

April 2013-April 2014 Monthly sampling at Penn Cove and Grayland Beach State Park

March 16- 27, 2012 UW Oceanography Senior Thesis Cruise. San Diego, CA to Manzanillo, Mexico. R.V. Thompson

October 8-19, 2011 Oceans and Human Health Cruise. R.V. Thompson

October 29-30, 2010 Oceans and Human Health Cruise. Puget Sound, WA. R.V. Thompson

November 17-19, 2009 Oceans and Human Health Cruise. Puget Sound, WA. R.V. Thompson

Summers 2007-2010 Shore based sampling expeditions in Puget Sound, WA, Washington, Oregon, and California coasts, and Kane'ohe Bay, HI.

OUTREACH AND BROADER IMPACTS

2015 Graduate Recruitment, Retention and Diversity (GRRAD) committee member

2012-2015 Mentor for students in the Genomics Outreach for Minorities, Alliances for Learning and Vision for Underrepresented Americans (GenOM ALVA)

Biosketch

Michael Curtis Grier Carlson was born in 1986 in Claremont, CA. His parents, Catharine Grier Carlson and Mark Carlson, were both Presbyterian ministers. He attended Pomona College in Claremont, CA, after which he attended the University of Washington, in Seattle, WA.

Michael's interest and passion for the ocean began early, spending summers at the beach with his grandparents swimming, sailing, lifeguarding, and working at an aquarium shop. He was inspired to understand the ocean during trips to Hawaii where he spent his time on coral reefs. In 6th grade, he forayed into marine biology during a summer course at the Polytechnic School. There, with friends, the life-long dream to pursue marine science was crystalized. In the summer his junior year at Pomona College, Michael interned at the Hawaii Institute of Marine Biology at the University of Hawaii where he research viruses on coral in Kane'ohe Bay. Being excited enough to wake up at 7 every morning (a feat for him), Michael decided to pursue marine science research. He continued his passions at the University of Washington studying viruses that infect marine phytoplankton.

Michael's passions have always been dual, driven by the need for balance. He competitively swam and played tennis. He plays the harp and paints. He majored in biology and history at Pomona College. He studied viruses and their hosts of his Ph.D. He continues this theme as a postdoctoral scholar at the Technion University in Israel studying marine cyanobacteria and their viruses.
