FOREWORD

ABSTRACT

Preliminary procedures for conducting a sperm bioassay using gametes from green sea urchins (Strongylocentrotus droebachiensis) and sand dollars (Dendraster excentricus) are outlined. Sperm bioassays were generally conducted by exposing the sperm cells to a set of conditions (or toxicant) for 15-60 minutes before addition of the eggs for fertilization. Declining fertilization success was used as an indication of compromise to sperm viability.

Sperm bioassays of physical water quality parameters indicated that fertilization was generally successful at temperatures from 2 to 22°C, salinities > 24 ppt and pH values of 7.5, 8.0 and 8.5. Green sea urchin sperm appear to be slightly more sensitive to environmental variables than sand dollar sperm. Fertilization was generally successful in artificial seawater at salinities \geq 30 ppt.

Sea urchin sperm bioassays of silver in natural seawater yielded 15-, 30-, 60- and 90-min EC50 concentrations of 590, 171, 83 and 52 $\mu\text{g/l}$ silver by probit analysis. Silver concentrations of < 40 $\mu\text{g/l}$ in natural seawater appeared to be stimulatory as percent fertilization in these concentrations was greater than control fertilization. Sea urchin sperm were more sensitive to silver in artificial seawater than in natural seawater with 30- and 60-min EC50's of 51 and < 20 $\mu\text{g/l}$ silver.

Sand dollar sperm bioassays of silver in natural seawater yielded 15-, 30-, 60- and 90-min EC50 concentrations of 201, 124, 47 and 25 $\mu\text{g/l}$ silver. Sand dollar sperm were also more sensitive to silver in artificial seawater than in natural seawater with 30- and 60-min EC50's of 56 and 25 $\mu\text{g/l}$.

Sea urchin bioassays of the organochlorine pesticide endosulfan in natural seawater yielded 30-, 60-, 90- and 120-min EC50's of 353, 143, < 66 and 195 $\mu\text{g/l}$ in natural seawater. Endosulfan proved more toxic in artificial seawater with 30- and 60-min EC50's of 189 and < 101 $\mu\text{g/l}$.

Sand dollar sperm bioassays of endosulfan in natural seawater produced 30-, 60-, 90- and 120-min EC50's of 157, 151, 113 and 80 $\mu\text{g/l}$ endosulfan. Endosulfan proved less toxic in artificial seawater with 30- and 60-min EC50's of 193 and 184 $\mu\text{g/l}$.

In comparative tests, both sea urchin and sand dollar sperm proved more sensitive to silver and endosulfan than the eggs. Temperature and salinity interactions with silver and endosulfan were assessed in matrix design bioassays and summarized using response surface plotting. Additionally, the interactive toxicity of various concentrations of silver and/or

endosulfan was investigated in one test with sand dollar sperm. This test found that the toxicity of silver and endosulfan in combination was additive.

In comparative 96-h sea urchin embryo bioassays of silver and endosulfan in natural seawater retardation of development was first observed in approximately 50 $\mu\text{g}/\text{l}$ silver and 253 $\mu\text{g}/\text{l}$ endosulfan. Similar 72-h sand dollar embryo bioassays of silver and endosulfan in natural seawater showed retardation of development in concentrations as low as 25 $\mu\text{g}/\text{l}$ silver and 158 $\mu\text{g}/\text{l}$ endosulfan.

There was a high degree of similarity between sperm sensitivity in the short-term bioassays and the 72- or 96-h embryo tests. Results from 30- to 90-min sperm bioassays are in the range of sensitivity for many 48- to 96-h bioassays previously reported for aquatic animals.

ACKNOWLEDGMENTS

This research was supported by the U.S. Environmental Protection Agency (Grant No. R805839-91-1). The Municipality of Metropolitan Seattle (METRO) donated space and seawater intake facilities for the bioassay laboratory.

The authors wish to acknowledge the valuable contributions of Sam Felton, Water Quality Chemist, and Craig Olds of the College of Fisheries. The assistance of Tom Rice, Supervisor, West Point Sewage Treatment Plant, and his Assistant Supervisor, Bill Burwell, is greatly appreciated.

Access to the animal collection sites was provided by the New England Fish Company and the personnel of Kopachuck State Park.

The authors are indebted to William Lester, Humboldt State University, for suggesting the use of a sperm bioassay.

The authors also wish to acknowledge the continued interest and helpful suggestions of the Project Officer, Dr. Richard Swartz, and Dr. Donald Baumgartner, Chief, Marine and Freshwater Ecology Branch, Environmental Research Laboratory, Corvallis, Oregon.

SECTION I

CONCLUSIONS

Preliminary procedures for conducting a sperm bioassay have been defined using gametes from green sea urchins (Strongylocentrotus droebachiensis) and sand dollars (Dendraster excentricus).

The sperm bioassay is a static test which exposes sperm cells to test and control solutions for short periods of time (typically 15-120 minutes). Eggs are added to the test containers after the sperm exposure period has ended. Samples are then tabulated for fertilization success and the results analyzed by standard bioassay statistical methods.

The optimal environmental conditions for conducting sperm bioassays are: temperature 2-22°C; pH - 7.5-8.5; and salinities > 24 ppt. These conditions vary slightly depending on species. Sand dollar sperm appear to be slightly less sensitive to environmental variables (temperature, salinity and pH) than green sea urchin sperm.

Green sea urchin and sand dollar sperm are approximately as sensitive to silver and endosulfan in seawater as many other animals with the possible exception of fish in long-term tests and some invertebrate larvae.

We conclude from these tests that the sperm bioassay, coupled with proper chemical analytical techniques, has great potential for quick and sensitive assessments and monitoring of the toxicity of chemical substances in the marine environment. This test, used in conjunction with other short-term screening tests (*e.g.* the Ames microbial mutagen test), could help to establish indices of toxicity for a wide array of chemicals which would be used in setting priorities for further research, routine biomonitoring of receiving waters and regulatory action.

SECTION II
RECOMMENDATIONS

1. Additional research is needed to refine and optimize the sperm bioassay procedures for use both in standard laboratory toxicity screening tests and for biomonitoring of receiving water quality.
2. Additional testing is needed to define and control optimum sperm/egg ratios and number of replicates to reduce between-test variance.
3. Streamline the test protocol by investigating the use of disposable test tubes.
4. Definition of the chemical interactions (reaction rates and products) of toxic substances is needed to relate the corresponding biological responses to toxicants in natural seawater. Testing of a greater number of chemical compounds is needed.
5. The relationship between toxicity and dissolved organics in seawater require further testing. The use of artificial seawater may aid these investigations.
6. Testing should be extended to include two additional species of sea urchins (the purple urchin, Strongylocentrotus purpuratus and the red urchin, S. franciscanus) to determine if sperm from a variety of echinoids are of equal sensitivity to toxic chemicals.
7. Include in the test program a non-echinoderm marine invertebrate (like the oyster, Crassostrea gigas or mussel, Mytilus edulis) to determine between-phyla sperm sensitivities.
8. Comparative 96-h acute fish and invertebrate flow-through bioassays are needed to validate the sensitivity of the sperm bioassay to aid application to water quality criteria and regulatory action.

SECTION III

INTRODUCTION

GENERAL

Scientists charged with the responsibility of assessing, monitoring and regulating the use of toxic substances are being increasingly challenged by the proliferation of chemicals for a wide range of societal applications. Biological screening techniques which can be conducted rapidly at least cost and which retain maximum sensitivity are needed in conjunction with sensitive analytical chemical techniques. Various aspects of biological systems must be considered, including toxicity, mutagenicity, carcinogenicity and teratogenicity. The currently popular Ames microbial mutagenesis test (Ames *et al.* 1975, McCann and Ames 1976) is one example of a refined and powerful short-term bioassay. This test uses single-cell bacteria to predict the mutagenicity (and, to a large extent, carcinogenicity) of many chemicals to higher animals. This test is not entirely precise or absolute, but it does provide a valuable screening test that is quick and practical and has the additional benefit of providing valuable insight into basic biological functions and relationships.

Short-term tests in relation to toxicity that are as powerful as the Ames test are presently lacking. Life-cycle and larval-stage bioassays are possible alternatives, but these are very time-consuming and difficult to conduct and interpret. Enzyme bioassays are somewhat quicker and very sensitive, but discrete biochemical reactions are being analyzed rather than a functioning biological system.

The sperm cell is a functioning biological unit which has been the object of extensive research, especially in relation to sea urchins (Booolootian 1966, Tyler and Tyler 1966, Czihak 1975, Giudice 1973). Sperm cells have been successfully bioassayed with a variety of toxicants including metals (Lillie 1921, Hoadley 1923, Young and Nelson 1974, McIntyre 1973), petroleum (Allen 1971, Lönning and Hagström 1975), organic compounds (Hagström and Lönning 1973) and municipal wastewaters (Muchmore and Epel 1973, Stober *et al.* 1977, Stober *et al.* 1978). These studies have shown sperm cells to be sensitive to a variety of toxicants in short-term tests (*i.e.* minutes) at or below concentrations causing mortality in standard 96-h fish bioassays and often approaching the sensitivity of larval and life-cycle bioassays.

Based on this information, we are suggesting that a standardized bioassay procedure using echinoderm sperm cells be developed and used to provide a screening technique for the establishment of toxicity indices for

a wide array of chemical toxicants. Toxicity indices would be useful as general biological baseline data, for setting priorities for further research, biomonitoring of receiving waters and regulatory action.

The purpose of this research is to define a set of standard conditions for conducting bioassays with sea urchin and sand dollar sperm and to utilize this procedure to determine the toxicity of two distinctly different reference toxicants: a metal (silver) and an organochlorine pesticide (endosulfan).

CHEMISTRY

Silver

Silver occurs naturally in seawater at reported concentrations of 0.15 (Bryan 1971) and 0.28 (Waldichuk 1974) $\mu\text{g}/\text{l}$. Silver discharges to the oceans approximate 5×10^3 metric tons/year naturally and 7×10^3 metric tons/year from mining (Waldichuk 1974).

Silver nitrate is highly soluble in cold freshwater (1,200 g/l (Weast and Selby 1967)). The solubility of silver nitrate in seawater was not located in our review of the literature. However, Bryan (1971) indicates that when silver is added to seawater, silver chloride is the probable product and has a solubility of approximately 2.0-2.5 mg/l.

Endosulfan

Endosulfan ($\text{C}_9\text{H}_6\text{O}_3\text{Cl}_6\text{S}$) is the common name of the insecticide 6, 7, 8, 9, 10, 10-hexachloro-1, 5, 5a, 6, 9, 9a-hexahydro-6, 9-methano-2, 4, 3-benzodioxathiepine-3-oxide, or α , β -1, 2, 3, 4, 7, 7-hexachloro-bicyclo-(2, 2, 1)-heptene-(2)-bis-hydroxymethylene-(5, 6)-sulfite, or 5-norbornene-2, 3-dimethanol-1, 4, 5, 6, 7, 7-hexachlorocyclic sulfite. It is formed by the Diels-Alder addition of hexachlorocyclopentadiene and cis-butene-1, 4-diol, followed by reaction of the addition product with thionyl chloride. Technical endosulfan is approximately a 7:3 mixture of two stereoisomers, α (alpha) and β (beta) endosulfan (α endosulfan is synonymous with endosulfan 2, A, I and Thiodan A or I. β endosulfan is synonymous with endosulfan B, II or Thiodan B or II). The melting point for the technical material is 80-90°C (Maier-Bode 1968). The reported solubility at 22°C and pH 7.2 in tap water is 0.15 mg/l for α endosulfan and 0.06 mg/l for β endosulfan (Braun and Frank 1973). At 20°C the solubility in acetone is 33 percent, in chloroform 50 percent, in ethanol 5 percent and in methanol 11 percent (Maier-Bode 1968).

The principal degradation products of endosulfan are endosulfan sulfate and endosulfan diol. Other products include endosulfan ether, endosulfan hydroxy ether and endosulfan lactone (Maier-Bode 1968).

Endosulfan is marketed under the trade name Thiodan and its potent insecticidal properties are directly primarily against the Colorado potato beetle, flea beetle, imported cabbageworm, peach tree borer, tarnished plant bug as well as various species of aphids and leafhoppers.

Silver

Silver is one of the most toxic metals to microbes and aquatic animals, yet it is relatively non-toxic to man and terrestrial vertebrates. Silver has been shown to be the most toxic heavy metal to bacteria (Albright *et al.* 1972), fish and invertebrates (Amiard 1976, Jones 1964), and usually followed closely by mercury in toxicity.

Silver is unusual among metals in combining very low solubility for most of its compounds with exceedingly high toxicity of the soluble fraction. For silver to be toxic in low doses, the ionic form (Ag^+) must come into direct contact with metabolically active sites such as cell membranes or gas exchange surfaces. The biological action of silver apparently involves reversible chemical bonding with enzymes and other active molecules at cell surfaces. Binding of the -SH groups seems to be the principal mechanism of enzyme inhibition by formation of silver mercaptides (Cooper and Jolly 1970). The biological action of silver has been found to be strongly dependent on temperature, oxygen, pH and hardness or salinity.

Silver has been found to be toxic to bacteria in 30-min exposures at a concentration of 1 $\mu\text{g}/\text{l}$ (Albright *et al.* 1972) and affects biological oxygen demand values by 50 percent at 0.3 mg/l (Sheets 1957).

Silver concentrations toxic to crustaceans have been determined for the crab, Carcinus maenas (adult 96-h LC_{50} = 1-2 mg/l; zoea I = 0.01-0.1 mg/l) and the shrimp, Palaemon serratus (adult 96-h LC_{50} = 10 mg/l; zoea I = 0.2-5 mg/l) (Amiard 1976). Daphnia magna suffers immobilization in 5.1 $\mu\text{g}/\text{l}$ as AgNO_3 (Anderson 1948), while Clarke (1947) found 0.2 mg/l (as Ag_2SO_4) toxic to the barnacle, Balanus balanoides in 5-day tests.

Molluscs appear to be especially sensitive to silver. Embryo 48-h LC_{50} 's for the oyster, Crassostrea virginica and the clam Mercenaria mercenaria are reported as 5.8 and 21.0 $\mu\text{g}/\text{l}$ silver in static tests, respectively, and the scallop (Argopecten irradians) embryo 96-h LC_{50} was 33 $\mu\text{g}/\text{l}$ (Calabrese *et al.* 1977). Snails (Taphius glabratus) react to 100 $\mu\text{g}/\text{l}$ silver by retracting the foot (Harry and Aldrich 1963), while the mud snail, Nassarius obsoletus, shows distressed behavior and reduced oxygen consumption at 500 $\mu\text{g}/\text{l}$ silver (MacInnes and Thurberg 1973).

Fish also show a high sensitivity to silver. Ninety-six hour LC_{50} 's for rainbow trout, Salmo gairdneri, are reported by Hale (1977) as 28.8 $\mu\text{g}/\text{l}$ and by Davies *et al.* (1978) as 6.5 (soft water) and 13.0 (hard water) $\mu\text{g}/\text{l}$. Goettle and Davies (1978) have recorded 96-h LC_{50} 's for fathead minnows, speckled dace and mottled sculpin as 3.9, 4.9 and 5.3 $\mu\text{g}/\text{l}$ in soft water and 4.8, 13.6 and 13.6 $\mu\text{g}/\text{l}$ in hard water, respectively. Silver concentrations of 70 $\mu\text{g}/\text{l}$ are acutely toxic to bass in 24-h (Coleman 1974). Long-term exposures (10 months) of rainbow trout have yielded a "no effect" level between 0.18-0.40 $\mu\text{g}/\text{l}$ Ag (Goettle and Davies 1978), while Jones (1939) defines the chronic threshold level for sticklebacks, Gasterosteus aculeatus, as 3 $\mu\text{g}/\text{l}$.

Endosulfan

Aquatic organisms differ considerably in their sensitivity to endosulfan and its metabolites. Fish appear to be the most sensitive group of organisms, generally having short-term LC50's in the range of 1 to 25 µg/l, although a 24-h LC50 as low as 0.02 µg/l has been reported for the harlequin fish (Rasbora heteromorpha) (Alabaster 1969). Knauf and Schulze (1973) tested several groups of organisms and found fish to be 10,000 times more susceptible to the toxic action of endosulfan and its metabolites than worms or snails. The increasing order of sensitivity was worms < snails < crabs < insects < fish. This order of sensitivity was similar for the two isomers α and β endosulfan and the sulfate. However, all groups were equally sensitive to the non-sulfur containing metabolites of endosulfan. The 48-h LC50's calculated for these metabolites were a minimum of 10³ times greater than those obtained with the sulfur compounds.

The reported toxicities of endosulfan to crustacea range from 24-h LC50's of 1 µg/l for Carinoganunarus rocsellii to 300 µg/l for Daphnia magna (Oeser *et al.* 1971). Insects, while generally less susceptible than fish, do have a few members within the group that are affected by low levels of endosulfan. Sanders and Cope (1968) determined the 96-h LC50 for stonefly naiads (Pteronarcys californica) to be as low as 2.3 µg/l though later instars of the naiads were more resistant. Annelida and mollusca 48-h LC50 values have been reported to be in the order of several mg/l (Oeser *et al.* 1971).

Aquatic plants appear relatively resistant to endosulfan and its metabolites. Knauf and Schulze (1973) have shown that the metabolism of algae was unaffected during a 5-day continuous exposure to 1-2 mg/l endosulfan.

Several water quality and biotic factors are known to influence endosulfan toxicity. Macek *et al.* (1969) point out the importance of temperature in evaluating toxicity. Exposure of rainbow trout (Salmo gairdneri) to endosulfan at 1.6, 7.2 and 12.7°C resulted in 24-h LC50's of 13, 6.1 and 3.2 µg/l, respectively, indicating an increased susceptibility at higher temperatures. Schoettger (1970) found similar temperature effect with rainbow trout and western white sucker (Catostomus commersoni). Changes in salinity have increased the toxicity to guppies (Lebistes reticulatus) (Greve and Verschuuren 1971); however, when guppies were first adapted to seawater the toxicity of endosulfan in seawater and freshwater was not appreciably different (Oeser *et al.* 1971). Additionally, Knauf and Schulze (1973) found no significant difference in endosulfan toxicity to the golden orfe (Idus melanotus) in freshwater or seawater. Schoettger (1970) considered pH the most important water quality parameter affecting toxicity. In studies involving the western white sucker, the aging of alkaline (pH 8.4) solutions of endosulfan for 48-h significantly reduced the toxicity compared with solutions of a similar concentration of neutral or slightly acidic pH's.

Schoettger (1970) also investigated the influence of biotic factors on toxicity and found older and heavier fish to be more resistant to endosulfan. However, concentrations of endosulfan of up to 50 mg/l in 30- or 120-min

exposures did not affect the hatchability of rainbow trout eggs nor subsequent survival of the fry.

SECTION IV

MATERIALS AND METHODS

GENERAL

All bioassays were conducted at the Fisheries Research Institute's Mobile Bioassay Laboratory located at the West Point Sewage Treatment Plant, Seattle, Washington.

Test Animals

Green sea urchins (Strongylocentrotus droebachiensis) were collected from a rocky breakwater in Elliott Bay, central Puget Sound, at a depth of 1-5 m below mean lower low water. Animals for general bioassay use were held in ambient flowing seawater while a second group was held in cooled flowing seawater to assess the effects of lower temperatures on gamete availability both early and late in the spawning cycle. Both groups were fed algae free-choice.

Sand dollars (Dendraster excentricus) were collected from a sandy beach in southern Puget Sound from approximately mean lower low water level and maintained in ambient flowing seawater on sand substrate. Plankton and detritus in the ambient seawater and sand substrate provided the only food supply.

Spawning and Gamete Quantification

The test animals were spawned separately by Tyler's (1949) KCl method (0.5-1.0 ml KCl injected through the peristomal membrane into the coelomic cavity). Sperm were collected in 100 ml fresh seawater and kept in this concentrated condition until just prior to use. Eggs were collected in 100-250 ml fresh seawater and washed 2-3 times before use. All gametes were kept cool in an ambient water bath (see Appendix Table and Figure 1).

Subsamples of sperm were counted by compound microscope and hemacytometer at 400X after fixing in 10 percent acetic acid in seawater. Subsamples of eggs were counted using a dissecting microscope at 10-20X.

Unless noted otherwise, sperm were diluted to a final concentration of 50×10^6 /ml and eggs diluted to 5×10^3 /ml. Most bioassays were conducted using 0.1 ml aliquots of sperm solution in 25 ml of test solution with the subsequent addition of 1 ml aliquots of egg solution. This combination produced a final sperm/egg ratio of 1000/1 and dilution of the test solutions of 0.4 percent upon sperm dosing and 4.0 percent during egg addition.

Sperm Bioassay Procedure

Most sperm bioassays were conducted by adding 0.1 ml aliquots of sperm solution to 25 ml replicate test and control solutions contained in 25 x 150 mm glass test tubes held in a circulating water bath of desired temperature. After an appropriate incubation period (typically 15-60 min) 1.0 ml of eggs was added to the sperm-toxicant solution and fertilization allowed to proceed for 15 min. The test tubes were then carefully decanted and the settled eggs poured into labeled vials containing 10 percent formalin in seawater for sample preservation and storage. The term "sperm exposure time" as used in this report is defined as the time between sperm addition to the toxicant and subsequent addition of the eggs. The sperm (and eggs) are exposed to the toxicant an additional period of time while fertilization (if any) takes place. This "extra" period of exposure is presently of undefined duration but should remain constant between bioassays using the same sperm-egg contact time interval.

Each egg sample was later tabulated for percent fertilization by re-suspending the eggs in each vial, pouring the contents onto a grid-lined glass slide and scoring 100 eggs for presence or absence of the fertilization membrane. Partially-formed membranes were tabulated as unfertilized eggs. Occasional broken membranes which otherwise appeared complete were counted as fertilized (Appendix Figure 1).

Embryo Bioassays

Embryo bioassays were conducted in a series of 250-ml glass beakers each containing 100 ml of test solution or control dilution water. Each concentration was duplicated. The bioassays were initiated by inoculating each container with approximately 5,000 freshly fertilized eggs. Development was allowed to proceed for 72 or 96 hours. Temperature control was maintained by an ambient water bath. At 72 or 96 hours the samples were fixed and stored in 10 percent formalin in seawater. Stirring or aeration of the test containers was not required. Mortality was assessed by comparing triplicate subsample counts of embryos from each container at 72 or 96 hours with triplicate subsample counts from two extra initial control samples.

Stages of embryonic development and abnormalities were assessed in subsamples of 100 embryos using a compound microscope at 40X and descriptions by Hagström and Lönning (1973), Kobayashi (1971), Okubo and Okubo (1962) and Rulon (1956).

Water Quality Control

The natural seawater used in most bioassays was pumped from Puget Sound from a depth of approximately 10 m by a 7.5 hp cast-iron pump. All supply and distribution lines were PVC plastic (conditioned in seawater for 3+ years). The laboratory head tank was fiberglass. Prior to use in bioassays, all natural seawater was filtered through a 5µm cellulose filter cartridge and an activated carbon cartridge.

Salinity was measured \pm 0.1 ppt with a Beckman RS-5 salinometer or hydrometer. Lower salinity solutions were prepared by dilution with fresh tap water dechlorinated with activated carbon or deionized water.

Temperature was measured with a thermometer graduated to 0.1° Celsius and controlled during bioassays with either an ambient temperature water bath or a heating/cooling circulating water bath.

Monitoring of pH was with an Orion specific ion/pH meter and pH electrode. Any required pH adjustments of the bioassay test or dilution water were made with gradual additions of either reagent grade HCl or NaOH to the desired pH.

Artificial seawater used in several bioassays was a commercial mixture called Marine Environment. This solution was filtered (0.45 μ m) and adjusted to the appropriate salinity and pH before use.

Acclimation and conditioning of green sea urchins to cooler than ambient water was accomplished with 1.0 hp Frigid Unit water chiller in a slow flow-through system.

SILVER BIOASSAYS

Silver test solutions were freshly prepared by appropriate additions of 100 or 1000 mg/l stock solutions of reagent grade AgNO₃ in distilled water to a measured volume of seawater. Each test solution was then split into replicate 25 ml bioassay samples and a sample for chemical analysis. This procedure was repeated until all test concentrations were prepared with the desired number of replicates. Simultaneously, other test solutions were prepared in precisely the same manner using a certified commercial silver reference solution (1 ml = 1 mg as silver). Samples of these solutions were retained for chemical analysis in conjunction with the AgNO₃ bioassay test solutions to provide a standard curve for comparison of the bioassay test concentrations by least squares regression analysis. Sperm or embryo bioassays were then conducted as outlined above.

The chemical samples were transported to the Fisheries Research Institute's Water Quality Laboratory at the University of Washington, where they were analyzed by flame atomic absorption spectrophotometry within six hours of sample preparation. Details of the instrumentation and methods are as follows:

| | |
|---------------|---|
| Instrument: | Perkin-Elmer 303 Atomic Absorption Spectrophotometer with DCRI Concentration Readout Assembly and Silver Lamp |
| Lamp Current: | 10 milliamps |
| Slit: | 4 |
| Wave Length: | 328.1 |
| Oxidant: | Air |
| Fuel: | Acetylene |

Other analyses of silver in freshwater or seawater under various laboratory conditions were conducted using the same instrument and methodology outlined above

ENDOSULFAN BIOASSAYS

Stock solutions were prepared by adding technical grade endosulfan (obtained from U.S. EPA Laboratory, Corvallis) in excess of its reported solubility (ca 250 µg/l) to prefiltered (0.45 µm) natural or artificial seawater. The stock solutions were filtered again and then diluted to form test solutions of desired concentrations which in turn were divided into replicate 25 ml test volumes and added to the bioassay tubes. The test solution from one of the tubes at each concentration was used only in the determination of the actual concentration of endosulfan at the initiation of each bioassay. Similar procedures were followed for α endosulfan, β endosulfan, endosulfan ether and endosulfan sulfate (obtained from FMC Corporation, Middleport, N.Y., and EPA, HERL, Research Triangle Park, N.C.).

Chemical analyses of endosulfan test solutions were performed as follows: the 25 ml water sample and approximately 10 ml of nanograde hexane were added to a 60 ml separating funnel equipped with a Teflon stopcock. The funnel was shaken vigorously and after phase separation the hexane was drained into a 50 ml volumetric flask. The water sample was extracted a second time with an additional 10 ml hexane, which was added to the first portion. The flask was brought to volume (which represented a 1:2 dilution) and approximately 3-4 g of anhydrous sodium sulfate was added. A portion of the extracted pesticide in hexane was transferred to glass tubes equipped with aluminum foil lined caps and stored until analyzed by gas chromatography.

The gas chromatographic operating conditions were as follows:

Instrument: Perkin-Elmer Model Sigma 1
Detector: 10 mC ⁶³Ni electron capture
Column: 6 ft x 2 mm I.D. glass column packed with 100/120 mesh Supelcoport coated with 3 percent SP-2100
Column flow: 40 cc 95 percent argon - 5 percent methane/minute
Detector flow: 65 cc 95 percent argon - 5 percent methane/minute
Temperature:
 Injector: 245°C
 Column: 230°C
 Detector: 300°C

Analytical reference standards of endosulfan (99.8 percent purity), α endosulfan (98 percent purity), β endosulfan (99 percent purity), endosulfan ether (100 percent purity) and endosulfan sulfate (100 percent purity) (obtained from EPA, HERL, Research Triangle Park, N.C. and FMC Corporation, Middleport, N.Y.) were used in constructing standard curves and monitoring the performance of the gas chromatograph.

SPERM BIOASSAY DATA ANALYSIS

Generally, each sperm bioassay conducted under a specific set of conditions was replicated four times using sperm from four separate males. This experimental design yielded four EC50 estimates per test condition, which took into consideration any variability due to differences in sperm quality and the counting-dilution error relating to sperm dosing.

All sperm bioassay responses (percent eggs fertilized) to be used for EC50 calculations were corrected for natural responsiveness of the controls by Abbott's formula (Step 12, Appendix Table 1) (Finney 1971). The corrected responses were used for the EC50 calculations using the BMD03S computer program for probit analysis with an attached FORTRAN program to calculate 95 percent fiducial limits for each EC50 by the methods of Litchfield and Wilcoxon (1949). Average EC50's were then calculated for each set of replicate EC50's by computing the mean and the 95 percent confidence limits based on the variability of the individual replicate EC50's. The mean EC50 \pm 95 percent confidence limits was then used as the basis for comparison of toxic effects between test conditions.

It should be noted here that 95 percent fiducial limits about an LC50 (or EC50) constitute a statement of probability that there is one chance in twenty that an individual LC50 does not fall within specified limits. Fiducial limits are not confidence limits which can be used for comparison of between-test treatments. Fiducial limits are the result of applying a transformation (usually the probit transformation) to percent mortality to create a linear relationship between mortality and log concentration using non-normal distributed data from bioassays. Calculation of confidence limits requires that the data approximate a normal distribution. A population of individual estimates of an LC50 should fit a normal distribution. Thus, 95 percent confidence limits may be calculated for the mean of the individual EC50's. The methods and discussion presented above closely follow the recommendations of Hodson *et al.* (1976).

SECTION V

CHEMISTRY

SILVER

Solubility

Tests were conducted to determine the solubility of silver (as AgNO_3) in seawater and its efficiency of measurement by flame atomic absorption spectrophotometry (AAS) as compared with freshwater. Test results of silver added to freshwater and seawater samples (12°C) show that the recovery of silver is linear up to the highest concentration of 2.5 mg/l in freshwater. Recovery of silver is somewhat less linear and begins to decline above 2.0 mg/l in seawater (Figure 1). Filtered ($0.45\ \mu\text{m}$) silver-freshwater solutions again show a linear concentration-absorbance relationship with only a slight loss of silver due to filtration. Recovery of silver from $0.45\ \mu\text{m}$ filtered silver-seawater samples is linear up to approximately 1.0 mg/l silver, after which silver measurements remain constant at approximately 165 absorbance units ($\sim 1.0\ \text{mg/l}$ silver). Thus, the apparent solubility of silver in seawater at 12°C is approximately 1.0 mg/l.

Effect of Filtration Pore Size

Filtration of silver-spiked seawater with a series of small-pore-size filters produced interesting results. Filtration of 1.0 mg/l silver solutions with filters ranging from 0.1 to $5.0\ \mu\text{m}$ pore size did not change the recovery of silver by AAS (Figure 2). Hence, silver, when added to seawater at concentrations $\leq 1.0\ \text{mg/l}$, is probably all in solution or in a colloidal state too fine to filter. Additions of silver $\geq 1.5\ \text{mg/l}$ show essentially constant recovery of silver with filtration at 1, 3 and $5\ \mu\text{m}$ pore sizes, and decreasing recovery of silver as pore size decreases below $1\ \mu\text{m}$. This indicates that there is a continuum of particle size from approximately $1.0\ \mu\text{m}$ to very-fine colloidal. The 3.0 mg/l silver concentration (Figure 2) was interesting because the recovery of silver after $0.1\ \mu\text{m}$ filtration was less than would be expected to be in silver solutions of 1.0 mg/l. Evidently, the relatively large colloidal fraction scavenged some of the silver which would normally be in solution under these test conditions (Temp. = 12°C , pH = 7.7, salinity = 29.8 ppt). Also of interest is that filtration of samples to be used in biological assays with the standard $0.45\ \mu\text{m}$ filter would leave a large component of colloidal silver in samples dosed with $> 1.0\ \text{mg/l}$, which may not exert a direct toxic effect in the assay, but still be measured (in part) by AAS.

Figure 1. AAS recovery of silver concentrations in freshwater (FW) and natural seawater (SW) before and after passage through a 0.45 μ m filter.

Figure 2. AAS recovery of silver concentrations of 1.0, 1.5, 2.0 and 3.0 mg/l in natural seawater after passage through filters with 0.1 to 5.0 µm pore sizes.

Effect of Temperature

The apparent limits of solubility (as determined by filtration at 0.45 μm) of silver in seawater were determined for four temperatures. The solubility of silver was approximately 1.1, 1.2, 1.5 and 2.0 mg/l at 7, 12, 17 and 22°C, respectively (Figure 3).

Effect of Salinity

The effect of various salinities on the recovery of silver by AAS was not entirely predictable. Measurements of silver added to distilled water (= 0 ppt) was linear and essentially complete (Figure 4). Recovery of silver was greater at 30 ppt salinity than at 20 ppt. Recovery of silver at 10 ppt fluctuated with dose but was similar to silver measurements at 20 ppt. Measurements were not made at salinities between 0 and 10 ppt, but it would be expected that recovery would gradually increase as salinity decreased until the measurements converge with the curve for distilled water.

Silver Concentrations in Biological Assays

Most sperm and embryo bioassays were conducted at silver concentrations < 500 $\mu\text{g/l}$. Hence, all silver in the bioassays should be in solution or in a colloidal state that would not be filtered by a 0.45 μm membrane filter. Occasional tests at or above the apparent saturation level of silver in seawater will be discussed later.

ENDOSULFAN

The absolute retention times of endosulfan ether, α and β endosulfan and endosulfan sulfate were approximately 1.1, 2.2, 2.8 and 3.4 minutes, respectively. Representative gas chromatograms of endosulfan standards and seawater extracts are presented in Figure 5. Solutions of endosulfan at pH 8.5 apparently degraded at a faster rate than those at pH values of 7.5 and 8.0. The appearance of a peak eluting prior to α endosulfan suggests the possible formation of endosulfan alcohol (Figure 6). However, only concentrations derived from α and β endosulfan peak areas were used in calculating the EC50 values for all bioassays.

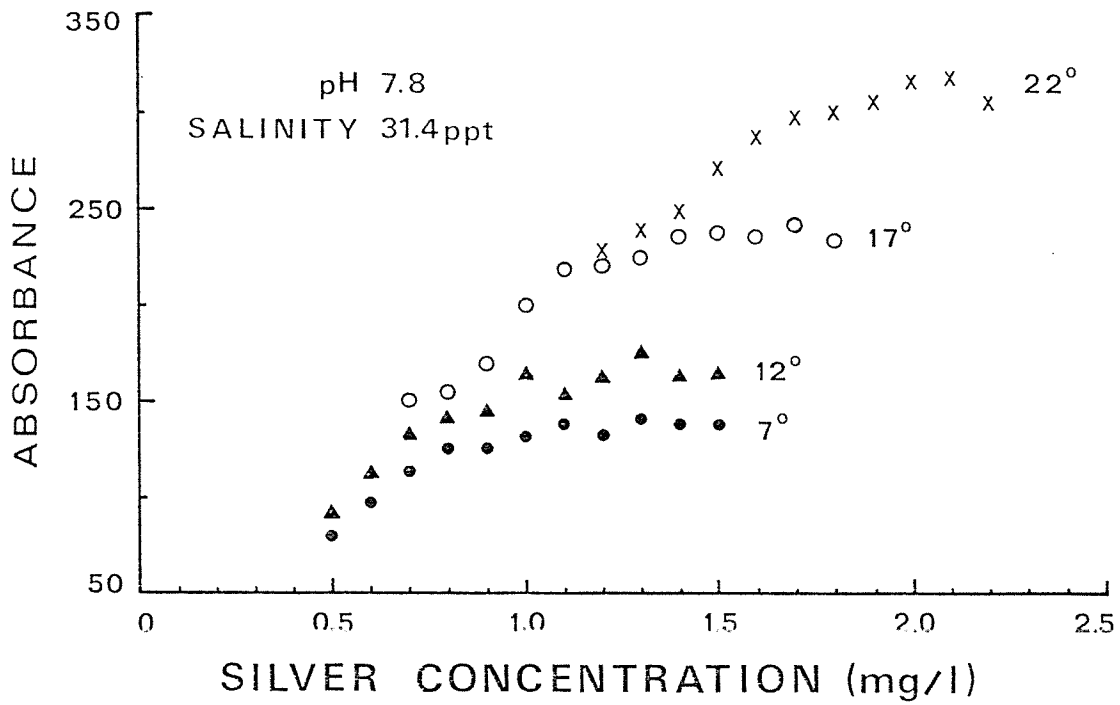

Figure 3. AAS recovery of silver in seawater at 7, 12, 17 and 22°C.

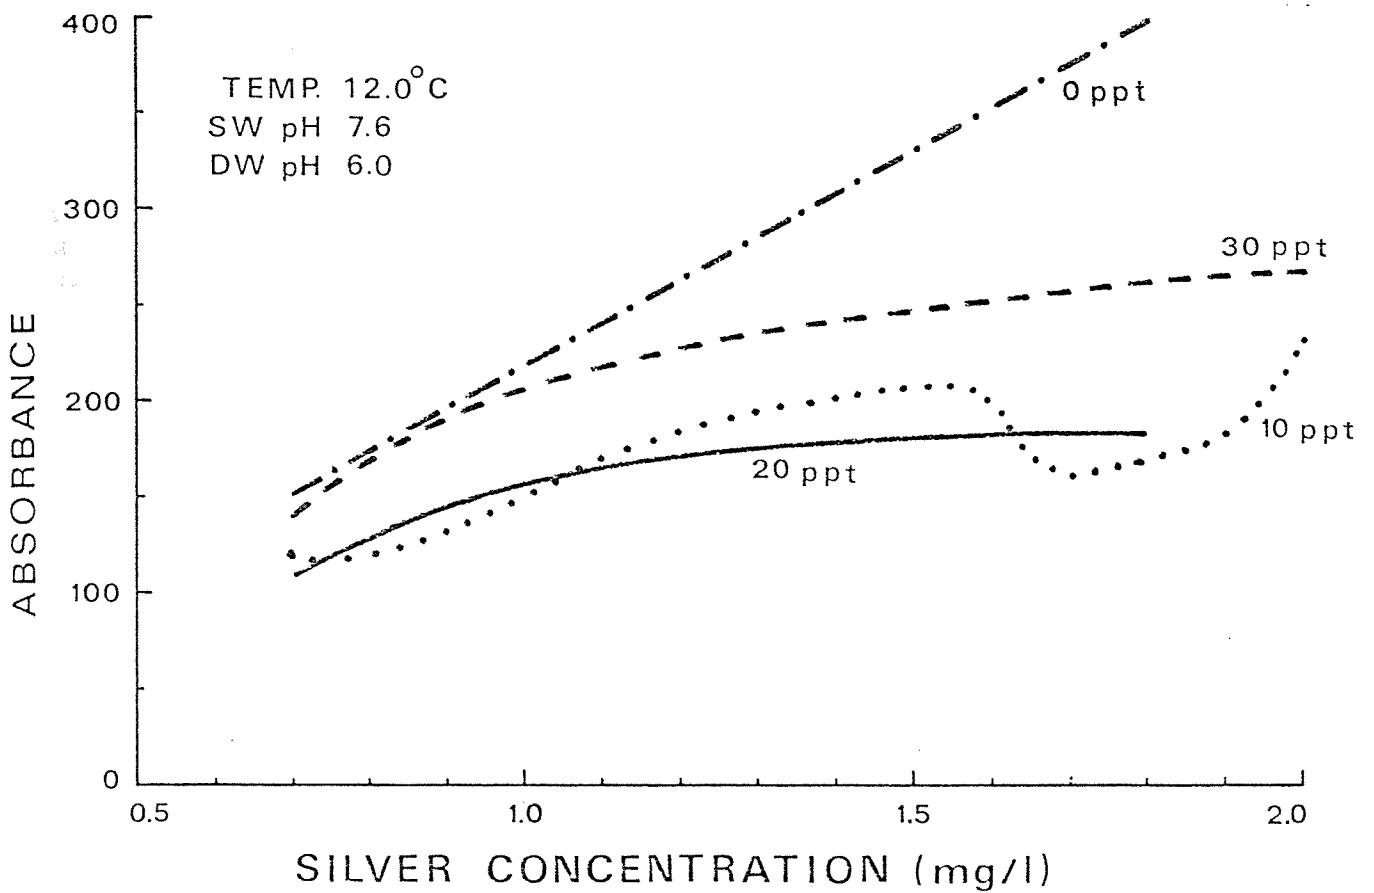

Figure 4. AAS recovery of silver in natural seawater at salinities of 0, 10, 20 and 30 ppt.

SECTION VI

GREEN SEA URCHIN BIOASSAYS

SPERM BIOASSAYS

Physical Parameters

Spawning--

Initiation of spawning activity in green sea urchins from the natural population in Elliott Bay and individuals conditioned in cooled seawater were monitored and compared. The first detectable spawning activity occurred on November 22 and December 12, 1978 for ambient and cooled sea urchins, respectively (Table 1). From November 5, 1978 to January 3, 1979 only males responded to the KCl injections. First female spawning occurred January 5, 1979. Essentially all animals were spawning by February 2, 1979. Animals which had been conditioned since October 25, 1978 did not spawn earlier than the natural population and lagged slightly behind them.

Egg production by KCl-injected females gradually increased from an average of 14,800 eggs/female on January 5, 1979 to 894,000 on February 12, 1979 (Table 2). Likewise, average percent fertilization of the eggs increased from low levels in January to 91.9 percent on February 12, 1979. Low fertilization success early in the spawning season was primarily due to a high percentage of immature eggs (indicated by the presence of a distinct nucleus) in the samples.

Eggs from females conditioned in cooled seawater did not show a distinct increase in either egg production or viability over the natural population. Equivalent samples on January 19, 1979 yielded an average egg production and fertilization success of 5,500 eggs/female and 18.2 percent fertilization for the natural population versus 23,000 eggs/female and 44.6 percent fertilization for the conditioned animals. Both groups fell short of the egg production and viability of the natural population recorded for February 2 and 12, 1979. Thus, it appears that a 2-3-month period of conditioning with cooled seawater was not successful in stimulating early gamete production in the sea urchins.

Termination of the active spawning period was apparently prolonged by the cool-water conditioning. Sea urchins maintained in ambient seawater showed the first signs of natural spawning on March 27, 1979. On April 2, 1979 90 percent of the individuals from this same group failed to respond to KCl injection. First signs of natural spawning in the conditioned animals was detected on April 11, 1979. However, a large proportion of these animals continued spawning for 4-8 weeks longer, with 50 percent of the

conditioned animals still spawning on June 8, 1979. Many of these animals had been spawned with KCl injection earlier in the season. This, in conjunction with the cooled water, may have helped to prolong spawning activity. The weekly averages of ambient temperatures and salinities and the conditioning water temperatures are presented in Figure 7.

Sperm and Egg Quantification--

Standardization of sperm and egg densities added to each bioassay test container is essential to reduce within- and between-test variability. Within-test variability is minimized by using equal aliquots of the same sperm and egg samples for all test containers in a bioassay test series. Between-test variability, however, is partially dependent on the technician's ability to reproduce the same concentrations of sperm and eggs from each set of animals throughout the spawning season.

Quantification of sperm and egg samples was normally done by microscopic counts of one or two subsamples of the concentrated gametes followed by dilution with a calculated amount of seawater (Appendix Table 1). To assess the accuracy of this procedure, five samples each of sperm and eggs were subjected to 10 replicate counts and the means, 95 percent confidence limits and ranges were recorded (Table 2). The 95 percent confidence limits show that the sample population means ($n = 10$) for sperm and egg counts should fall within ± 15 percent and ± 11 percent, respectively. However, since the population means of each sperm and egg batch are normally estimated by only one or two samples, the variation of individual counts becomes important. The range values (Table 3) show deviations from the sample means by as much as 46 percent for sperm and 41 percent for egg counts. Thus, using a target sperm/egg ratio of 5,000,000/5,000 ($= 1000/1$) for each bioassay container, the worst case counting-dilution error could produce a sperm/egg ratio of 2,700,00/7,050 ($= 383/1$) for a single subsample count. Based on sperm/egg ratio fertilization tests (see next section) a 383/1 sperm/egg ratio would be unsatisfactory for optimal control fertilization. Methods must be investigated for reducing or eliminating this large source of between-test variability to enhance the precision of the sperm bioassay.

Effect of Sperm/Egg Ratio--

Previous tests with sand dollars and sea urchins had suggested that a sperm/egg ratio of 1000/1 would generally produce > 90 percent fertilization in control samples for 5 to 15-min "exposure" ("exposure" = sperm time in dilution seawater prior to addition of the eggs) periods without decreasing the sensitivity of the test. To further clarify this relationship, sets of bioassays were conducted using 15-, 30- and 60-min sperm "exposure" periods and varying sperm/egg ratios in control seawater. The results of these tests suggest that the 1000/1 ratio may be satisfactory for 15-min sperm "exposure" periods, but that 30- and 60-min "exposure" periods may require a higher sperm/egg ratio to yield consistently high control fertilization (Figure 8). The 15-min "exposure" tests yielded > 90 percent fertilization down to a 640/1 ratio. Fertilization in the 30- and 60-min tests was < 90 percent below a ratio of 2560/1. The values plotted in Figure 8 represent averages of several tests. There was a rather high variability in the results of replicate tests at the same "exposure" time. Several 30- and 60-min "exposure" tests showed > 90 percent fertilization at a ratio of

Figure 7. Weekly average seawater temperatures (ambient and from the sea urchin conditioning tank) and salinity measured at the West Point Laboratory.

| 5 | 8030.0 ± 339.5 | 7000 - 8700 |

Figure 8. Average fertilization success after 15-, 30- and 60-min sperm "exposures" to natural seawater at sperm/egg ratios of 10-5120/1.

1280/1 while other replicates were substantially < 90 percent. The reasons for this variability are not totally known but may include: 1) counting-dilution error, 2) gamete quality, 3) slow activation of the sperm and 4) inhibition of sperm by egg secretions (egg water).

Subsequent tests with silver and endosulfan were conducted at a sperm/egg ratio of 1000/1 so that these tests could be related to those previously conducted at this ratio, and to maintain a base level of sensitivity for the test. The results of those tests which did not exhibit optimal control fertilization were related to the control fertilization by adjusting all results to the percent of control fertilization (i.e. control = 100 percent). This was necessary with the data in Figure 8 (5120/1 = 100 percent) as the presence of 10-20 percent immature eggs reduced the maximum possible fertilization to < 90 percent.

Sources of Variability--

As mentioned in previous sections, there are several factors that may affect the within- and between-test variability. Three sets of tests were conducted to assess variability associated with difference combinations of eggs and sperm and to test the uniformity of replicate samples within tests.

One test series used sperm from 10 different males to fertilize eight replicate samples each of eggs from a single female. The mean percent fertilization and standard deviation for each set of replicates is summarized in Table 4. The average fertilization for all 10 tests was 94.7 percent with a narrow average standard deviation of 2.1. A second test series using eggs from 10 different females fertilized by sperm from only one male produced essentially the same results with an average fertilization of 94.1 percent and an average standard deviation of 2.6 (Table 4). In both of these tests the individual replicate standard deviations fell between 1.1 and 4.8 indicating a fairly uniform response in each replicate sample.

A third set of 10 tests conducted over a longer period of time matched 10 males with 10 females on a one-to-one basis to approximate the normal between-test control pattern. This test series produced a lower fertilization success (average = 77.3 percent) and higher replicate variability (average standard deviation = 6.1) (Table 4). The bulk of these tests were conducted early in the spawning season when some immature eggs were present in the samples, thus causing a reduction in fertilization success. However, the high individual standard deviations suggest other factors may also be important. The counting-dilution error discussed in a previous section would be greatest in this third test since all gametes of one sex or the other came from a single batch in the first two tests, thus reducing this type error by approximately 1/2. Another factor causing higher variability is that the fertilization success in the third test series was closer to the mid-point of the response curve. As one approaches the limits of the response curve (i.e. 0 or 100 percent) variability would be expected to decrease since the situation is changing from a dose-response effect to an all-or-none response.

These tests reinforce the need for optimal control fertilization (which minimizes the control variability) so that toxicant dose-response curves

Table 4. Average percent fertilization (\bar{x}) and standard deviations (σ) of three test series using three different combinations of male and female sea urchins. Each test entry represents eight replicate samples.

can be analyzed by standard probit analysis without compromising data transformations. Factors which affect the control fertilization should be further investigated to enhance the reproducibility of the sperm bioassay.

Sperm and Egg Quality Through Time--

Optimal control fertilization depends on the availability of healthy, viable gametes. Early in the spawning season fertilization of the eggs may be less than optimal due to the presence of immature eggs. Late-season gametes may be less viable due to resorption of the gonadal tissue after normal spawn-out time. Gamete viability is also a function of time after initiation of spawning. Sperm are "activated" by dilution into seawater during spawning, the amount of activation being partially dependent on the amount of dilution and various water quality parameters (i.e. salinity, temperature, trace metals, etc.).

Two tests were conducted to measure the length of time that the gametes remained viable after induced spawning with KCl. Tests conducted on February 12 and May 2, 1979, utilized replicate samples of 10 and 8 male-female pairs, respectively. Water temperature was 7.7°C, pH 8.1 and salinity was 29-30 ppt during each test series. The sperm and eggs were maintained at normal test concentrations (sperm = 5,000,000/ml; eggs = 5000/ml) during the 72-h test period. Sperm "exposure" to control seawater prior to egg addition was 15 min.

Both tests showed approximately 90+ percent fertilization up to 24 hours (the February 12 tests showed high variability with 9.0- and 15.0-h tests yielding only 88 and 79 percent fertilization, respectively) (Figure 9). Surprisingly, fertilization was still partially successful at 48 and 72 hours, although < 90 percent. The May 2 test series suggests that sperm may not be fully activated under the above test conditions for several hours as average fertilization success gradually increases from 92.3 percent at 1.5 hours to 98.0 percent at 7 hours.

Average fertilization in the May 2 test series was consistently higher and less variable than in the February 12 tests. This again suggests that mid- to late-season gametes are more dependable test "organisms" than early-season gametes. Egg maturity has already been mentioned as one factor affecting early-season viability. Other possible factors affecting early viability were not specifically investigated but may include physical water quality parameters, food supply and possible endogenous biochemical factors of the gametes themselves.

Temperature, Salinity and pH--

Sets of bioassays were conducted in natural seawater to define the ranges of temperature, salinity and pH which would normally allow optimal fertilization in the absence of toxicants.

Temperature bioassays conducted at 28 ppt salinity and pH 8.0 show that fertilization is generally successful from 2-17°C for 30-min sperm "exposures". Fertilization dropped to only 7.5 percent at 22°C (Figure 10). (Sand dollar and sea urchin data are shown in Figures 10, 11 and 12 to facilitate comparison, but sand dollar results will be discussed in a

Figure 9. Long-term viability of sea urchin sperm held at concentrations of 50×10^6 /ml of natural seawater as indicated by average fertilization success over a 72-h time period.

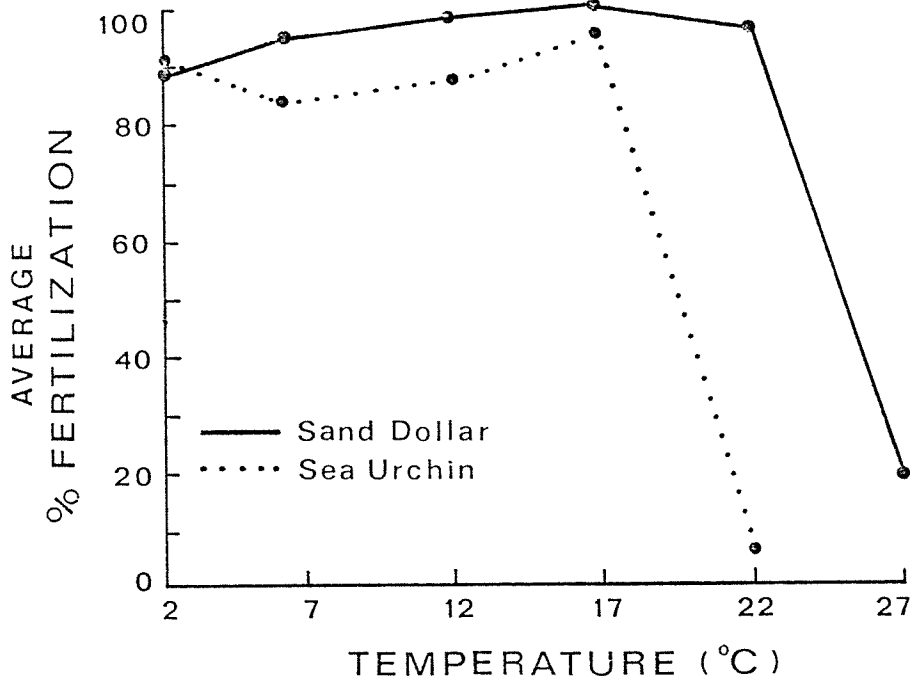

Figure 10. Average percent fertilization after 15-min "exposures" of sand dollar and sea urchin sperm to natural seawater at 2, 7, 12, 17, 22 and 27°C.

Figure 11. Average percent fertilization after 15-min "exposures" of sand dollar and sea urchin sperm to natural seawater at salinities from 0-30 ppt.

following section.)

Salinity bioassays at 12°C and pH 8.0 produced essentially no fertilization success at salinities < 20 ppt with increasing fertilization from 22-29 ppt for 15-min sperm "exposures" (Figure 11). The apparently linear relationship between salinity and fertilization and the less than optimal fertilization at 29 ppt (85.5 percent) in this test series suggests that sea urchin gametes may require salinities > 29 ppt. Ambient salinities at the West Point Laboratory were typically in the 27-29 ppt range during most sea urchin sperm bioassays. Thus, some of the variability and sub-optimal fertilization in tests controls may have been due to salinity stress. This situation can possibly be corrected in future tests by obtaining higher-salinity natural seawater from another location or by using artificial seawater of ≥ 30 ppt.

Bioassays of varying pH at 12.0°C and 29 ppt salinity showed generally poor fertilization at pH values ≤ 7.0 and ≥ 9.0 . Fertilization was sub-optimal at pH 7.5 and most successful at 8.0 and 8.5 for 15-min sperm "exposures" (Figure 12).

To assess the interactive relationship between salinity, temperature, pH and fertilization success, a matrix of tests at 4 salinities, 5 temperatures and 4 pH values was conducted in properly adjusted natural seawater. Generally, all tests at pH 7.0 showed negligible fertilization; tests at pH 7.5 reflected poor fertilization, and tests at 8.0 and 8.5 showed generally successful fertilization at the higher salinities (Figure 14).

Fertilization success showed a gradual decline in relation to salinity at pH values of 7.5, 8.0 and 8.5. This reinforces the above suggestion that optimal sea urchin fertilization requires salinities > 29 ppt.

Responses to temperature were inconsistent. Figure 14 shows a drop in fertilization success at 7°C in each plot. Whether this was a "real" response or an artifact of between-test variability is not known. Other than this inconsistency, fertilization was generally good from 2-17°C at the higher salinities and pH values. Fertilization was totally unsuccessful at 22°C.

Artificial Seawater--

Since fertilization did not appear to be optimal at ambient seawater salinities, one bioassay series was conducted comparing fertilization success in artificial seawater and natural seawater. With the exception of one test point (30-min "exposure" at 27.0 ppt salinity) fertilization was > 90 percent in artificial seawater in salinities of 25.2 to 36.2 ppt for 15- and 30-min sperm "exposures" (temperature = 8.5°C, pH = 7.9) (Figure 15). However, 60-min "exposure" to artificial seawater provided > 90 percent fertilization only at salinities ≥ 30.6 ppt. An equivalent test of sperm in natural seawater for 60 minutes showed similar fertilization responses at 28.8 and 27.0 ppt, but fertilization success in natural seawater was less than artificial seawater at salinities ≤ 25.2 ppt. These data reinforce the indication that salinities < 29 ppt are stressful to green sea urchin sperm and indicate that artificial seawater (≥ 30 ppt salinity) may

 Z-AXIS IS PERCENT FERTILIZATION

Figure 14. Response surface plots of average percent fertilization in a matrix design bioassay series at temperatures of 2, 7, 12, 17 and 22°C; salinities of 22, 24, 26 and 28 ppt; and pH's of 7.0, 7.5, 8.0 and 8.5 (see urchin).

Figure 15. Fertilization success after 15-, 30- and 60-min sea urchin sperm "exposures" to artificial seawater and 60-min "exposures" to natural seawater at salinities from 19.8 - 36.2 ppt.

provide an excellent test medium for the fertilization bioassay, especially when dilution water of a known standard composition is desirable.

Silver

Time-Concentration--

Sperm bioassays of silver in natural seawater were conducted with 20 silver concentrations and sperm exposure times of 15, 30, 60 and 90 minutes. Each test was replicated two to four times.

The EC50's decreased with each increase in exposure time. The calculated EC50's and 95 percent confidence limits at 15, 30, 60 and 90 minutes were 590 ± 1861 , 171 ± 13 , 83 ± 19 and 52 ± 37 $\mu\text{g/l}$ silver, respectively.

One factor which was not described by the EC50 analyses above is the apparent stimulatory effect of silver at concentrations less than the EC50 concentrations. The average plotted values for 30-, 60-, 90- and 120-min exposure tests clearly show higher than control fertilization for each concentration-response curve (Figure 16). This same effect was evident in most of the other sperm bioassays conducted with silver. The possible reasons for this low-level stimulation will be discussed later.

Sperm Versus Egg Sensitivity--

Tests were conducted to determine the relative sensitivity between sperm and eggs exposed to silver in seawater. Sperm exposed to silver for 30 minutes showed successful (> 96 percent) fertilization in concentrations of silver of up to 150 $\mu\text{g/l}$ and declining fertilization success in ≥ 175 $\mu\text{g/l}$ (Figure 17). When eggs only were exposed for 30 minutes, fertilization was successful in up to 200 $\mu\text{g/l}$ silver. Sperm and eggs exposed simultaneously for 30 minutes were generally more sensitive to silver than either sperm or eggs alone. Concentrations of silver as low as 50 $\mu\text{g/l}$ reduced fertilization success by approximately 50 percent.

A second test series focused on egg sensitivity to high concentrations of silver. This test showed that eggs remained viable for fertilization (≥ 95 percent) in silver concentrations as high as 8.0 mg/l. Eggs in 16.0 mg/l silver showed a reduction in fertilization to 38.5 percent, but "control" solutions of silver which were dosed with sperm and eggs simultaneously showed a similar reduction in fertilization at 16 mg/l. Thus, silver in seawater appears to affect primarily the viability of the sperm.

Effects of pH--

The toxicity of silver in seawater at pH 7.5, 8.0 and 8.5 was tested in one test series using sperm and eggs from one sea urchin pair and dosing duplicate samples for each silver concentration and pH. The EC50's and 95 percent confidence limits were essentially the same for each pH (Table 5). Thus, varying the pH of silver-seawater test solutions between 7.5 and 8.5 should not significantly alter the toxicity of silver.

Effects of Temperature and Salinity--

A matrix of bioassays was conducted using a range of silver concentra-

| 17 | 26 | 31 | 25 - 37 |
| 17 | 24 | <19 | — |

tions in seawater at 7, 12 and 17°C; 24, 26 and 28 ppt salinity; and pH 8.0. Response surface plotting shows an obvious decrease in fertilization success with increasing silver concentration (Figure 18). Fertilization also generally declines with decreasing salinity for a given silver concentration. As noted earlier, green sea urchin sperm are probably stressed by any salinities below about 29 ppt. The effect of temperature is not quite as obvious. There appears to be a greater sensitivity to silver at the higher temperature range at each salinity and at the low temperature range at 24 ppt salinity. These same trends are shown by the individual test EC50's listed in Table 6.

Artificial Seawater--

Thirty- and 60-min sperm bioassays of silver in artificial seawater suggest that silver may be more toxic in artificial seawater than in natural seawater. The average EC50 and 95 percent confidence limits for the 30- and 60-min tests were 51 ± 197 and < 20 $\mu\text{g}/\text{l}$ silver. These EC50 values are substantially less for equivalent EC50's in natural seawater (171 and 83 $\mu\text{g}/\text{l}$ for 30- and 60-min EC50's).

Endosulfan

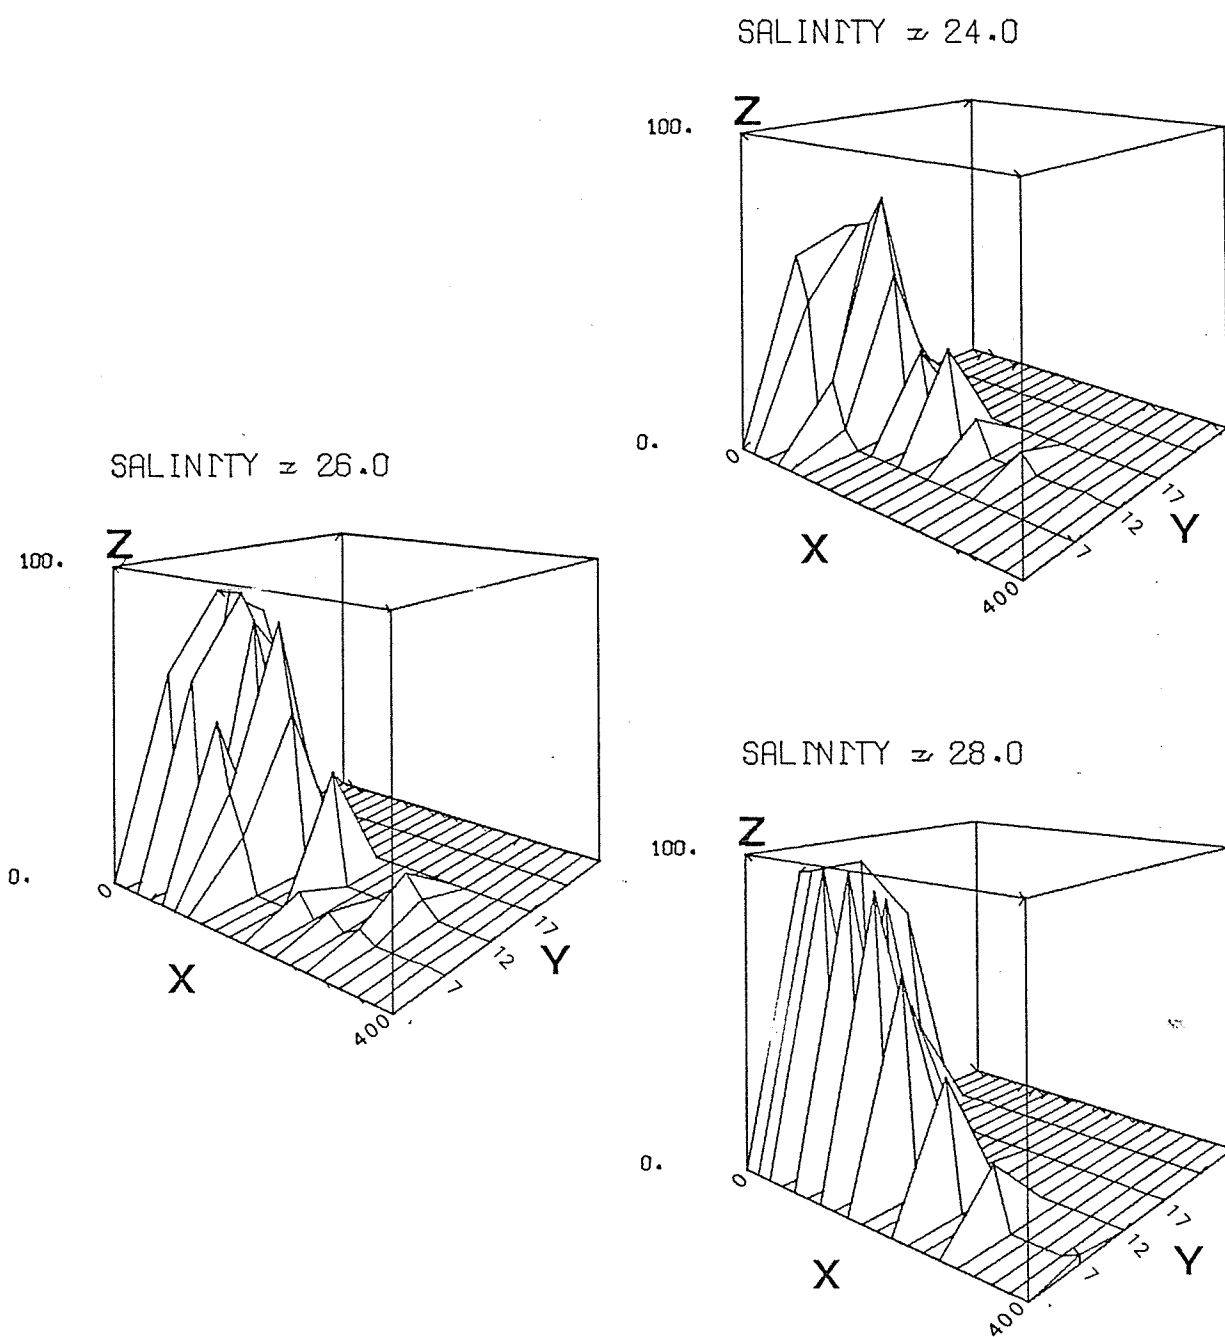

Time-Concentration Responses--

Sperm bioassays of endosulfan in natural seawater were conducted with nine endosulfan concentrations and sperm exposure times of 30, 60, 90 and 120 minutes. Each test was replicated four times.

The EC50 and 95 percent confidence limits of tests for 30-, 60-, 90- and 120-min exposure times were 353 ± 97 , 143 ± 160 , < 66 and 195 ± 102 $\mu\text{g}/\text{l}$ endosulfan. The EC50 calculations for the 90-min exposure times were highly variable or not possible to calculate. The percent fertilization for all concentrations from 65.9 to 291.5 $\mu\text{g}/\text{l}$ endosulfan in these tests was generally < 30 percent, making it difficult to calculate a regression equation.

The 90- and 120-min sperm bioassays utilized sperm/egg ratios of 2000/1 and 4000/1, respectively, in an attempt to maintain control fertilization at ≥ 90 percent. However, fertilization success in natural seawater controls for 90- and 120-min tests only averaged 10.5 and 53.0 percent, respectively. Reasons for poor control fertilization at the longer exposure periods are presently not known. Sperm senescence is one possibility. Even though concentrated batches of sperm maintain some viability for as long as 72 hours (Figure 9), it may be that activation is greatly enhanced (and thus, longevity reduced) when the sperm are diluted to $2 \times 10^5/\text{ml}$ in the test tubes. Another possibility is that the sperm have "sticky heads" which cause them to "plate out" with time on the sides of the test tubes, thus reducing the number of sperm available for fertilization.

The reasons for the lower toxicity response seen in the 120-min tests are not clear. Some variable factor (possibly dissolved organic material) in natural seawater which has a capacity for binding dissolved endosulfan may be responsible for the fluctuating toxicities seen in many of the endosulfan bioassays.

X-AXIS IS SILVER CONCENTRATION, 0-400 MICROGRAMS/LITER
 Y-AXIS IS TEMPERATURE, 1-24 DEGREES CENTIGRADE
 Z-AXIS IS PERCENT FERTILIZATION

Figure 18. Response surface plots of average fertilization success after 30-min sea urchin sperm exposures to a matrix design bioassay series of 0-400 $\mu\text{g/l}$ silver in natural seawater at 7, 12 and 17°C; 24, 26 and 28 ppt salinity; and pH 8.0.

One other factor which may have affected the results of the time-concentration bioassays was the presence of a small amount of acetone (approximately 20 $\mu\text{l/l}$) which was used as a solvent for the endosulfan in this test series. Fertilization in acetone-seawater controls was the same as in the normal seawater controls for the 30-min exposure tests and substantially greater for the 60-, 90- and 120-min bioassays. Acetone at a concentration of 20 $\mu\text{l/l}$ in seawater may have a stimulatory effect on the sperm and eggs.

A bioassay test series of acetone in natural seawater showed > 90 percent fertilization in acetone concentrations up to 50 $\mu\text{l/l}$ for up to 90-min bioassays. Fertilization was < 90 percent in acetone concentrations $\geq 100 \mu\text{l/l}$.

All other endosulfan bioassays were conducted without the use of acetone (or other carrier solvent) to eliminate any possibilities of acetone-induced toxicity or stimulatory effect.

Sperm Versus Egg Sensitivity--

Eggs exposed to endosulfan in natural seawater for 60 minutes showed successful fertilization in concentrations of up to 750.5 $\mu\text{g/l}$, which was the limit of solubility of endosulfan in the batch of seawater used for this test series. The primary toxicity of endosulfan is to the sperm and not the eggs.

Effects of pH--

The effect of varying seawater pH on toxicity of endosulfan was determined by testing duplicate sets of samples at pH 7.5, 8.0 and 8.5 with the same sperm and egg solution. Thirty-min sperm exposures yielded EC50's and 95 percent confidence limits of 401 ± 51 and $460 \pm 61 \mu\text{g/l}$ endosulfan for the pH 8.0 and 8.5 tests. No EC50 estimate was possible for pH 7.5 due to poor control fertilization. The present data do not lend themselves to comparisons of toxicity except to say that the toxicity is not substantially different between pH 8.0 and 8.5.

The EC50's determined for the pH tests are dependent on the forms of endosulfan that are used to calculate the amount of endosulfan in the samples. Normally, only endosulfan α and β isomers are used for the toxicity calculations. However, a third, presently unidentified form or degradation by-product (possibly endosulfan diol), is present in most bioassay samples analyzed by gas chromatography (GC). This unidentified form appears to vary with pH, being most prevalent at high pH values. In the endosulfan-pH test discussed above this third GC peak represents approximately 6, 12 and 43 percent of the total endosulfan at pH values of 7.5, 8.0 and 8.5 (Figure 6). Inclusion of this peak in the concentration calculations has the effect of increasing any individual EC50's by approximately 6, 12 and 43 percent at pH 7.5, 8.0 and 8.5, respectively. While any EC50 increases would be relatively minor at pH 7.5 and 8.0, the 43 percent increase at pH 8.5 produces a new EC50 of 582 versus 460 $\mu\text{g/l}$. Hence, the conversion of endosulfan α and β to this third form may decrease the toxicity of total endosulfan to sea urchin sperm.

Effects of Temperature and Salinity--

A matrix of bioassays was conducted using a range of endosulfan concentrations in seawater at 7, 12 and 17°C; 24, 26 and 28 ppt salinity and pH 8.0. Response surface plotting shows a decrease in fertilization success in both controls (0 µg/l) and endosulfan at 24.0 ppt salinity (Figure 19). Fertilization success was good in controls and low concentrations of endosulfan in 26.0 ppt salinity but decreased in the higher endosulfan concentrations (as compared with the response at 28.0 ppt salinity). Temperature interactions seemed to be an important factor only at 24.0 ppt salinity, where fertilization was nil in both controls and endosulfan at 17°C and in the endosulfan concentrations only at 12°C (Figure 19). The negative effect of increasing endosulfan concentration on fertilization is most clearly seen in the 26.0 ppt salinity plot. Fertilization was generally good in all but the highest concentrations at 28.0 ppt salinity. The average EC50's and 95 percent confidence limits of the endosulfan matrix bioassays are listed in Table 7.

Artificial Seawater--

Thirty- and 60-min sperm exposure tests were conducted with endosulfan dissolved in artificial seawater. The 30- and 60-min EC50's and 95 percent confidence limits of four replicate samples were 189 ± 78 and < 101 µg/l endosulfan, respectively. These values are somewhat less than the equivalent EC50's in natural seawater (353 and 143 µg/l).

Reasons for the possible increase of endosulfan toxicity in artificial seawater are not presently known. Degradation rates and products of endosulfan may be different between artificial and natural seawater. Unlike natural seawater, artificial seawater contains few dissolved organics which might complex with endosulfan. Further testing with natural and artificial seawater will be necessary to resolve the differences.

Summary of Sea Urchin Sperm Bioassay Data--

Individual and mean EC50's, fiducial limits, confidence limits and test conditions of silver and endosulfan bioassays are summarized in Appendix Tables 2 and 3.

EMBRYO BIOASSAYS

Silver

A 96-h bioassay of sea urchin embryos was conducted to determine the relative toxicity of silver to sperm and developing embryos. The results show that there was no evident effect on development at initial calculated silver concentrations of 3.12, 6.25, 12.5 and 25.0 µg/l (Figure 20). Retardation of development is evident at 50 and 100 µg/l. All embryos in 200 µg/l silver were killed at the post-hatch blastula stage and were undergoing cytolysis. Embryos in 400 µg/l silver were arrested in the pre-hatch 32-128 cell stages, but were still alive. Evidently, the embryos in the 400 µg/l silver were partially protected from its toxic effects by the fertilization membrane which remains intact until hatching. Embryos in the 200 µg/l silver were probably killed when they hatched out of this protective membrane.

Figure 19. Response surface plots of average fertilization success after 30-min sea urchin sperm exposures to 0-500 µg/l endosulfan in natural seawater at 7, 12 and 17°C; 24, 26 and 28 ppt salinity; and pH 8.0

TABLE 8. DEVELOPMENT PATTERNS OF SEA URCHIN EMBRYOS DURING A 72-HOUR EXPOSURE TO SILVER IN NATURAL SEAWATER.

| Silver (µg/l) | % Composition | | |
|---------------|---------------|----------|-------|
| | Blastula | Gastrula | Prism |
| 0 | 0 | 97 | 3 |
| 5 | 4 | 75 | 21 |
| 10 | 3 | 86 | 11 |
| 20 | 5 | 83 | 12 |
| 40 | 8 | 87 | 5 |
| 80 | 32 | 68 | 0 |

Figure 20. Percent composition of the stages of development of sea urchin embryos after 96-h exposures to 0-400 µg/l silver in natural seawater.

The retardation in development of embryos at silver concentrations of 50-100 $\mu\text{g}/\text{l}$ compares favorably with the 60- and 90-min sperm test EC50's of 83 and 52 $\mu\text{g}/\text{l}$. Sea urchin sperm appear to be as sensitive to low concentrations of silver in seawater in 60- and 90-min exposures as the developing embryos are in 96-h exposures.

The similarity in sensitivity between sperm and embryos is reinforced by an earlier preliminary 72-h embryo test with silver which was terminated before the embryos reached the pluteus stage. The results of this test showed accelerated development of embryos (i.e. more have reached the prism stage) in 5, 10 and 20 $\mu\text{g}/\text{l}$ silver; a normal development rate in 40 $\mu\text{g}/\text{l}$; and retardation of development in 80 $\mu\text{g}/\text{l}$ (Table 8). This same pattern of low-level silver stimulation was illustrated for the sperm bioassays in Figure 16.

Endosulfan

A 96-h sea urchin embryo bioassay of endosulfan in seawater resulted in only minor effects to the embryos over the range of concentrations tested. The embryos showed essentially the same pattern of development as controls in initial concentrations of endosulfan of 63.0 - 231.6 $\mu\text{g}/\text{l}$. Development was slightly retarded in 264.9 and 253.1 $\mu\text{g}/\text{l}$ (Figure 21). Final concentrations of endosulfan measured in the test beakers after 96 h were an average of 67.2 percent lower than initial values. Hence, it is difficult to define an exact concentration of endosulfan which may have produced the retardation in the two highest concentrations. However, it is evident that some concentration of endosulfan between 67.5 and 264.9 $\mu\text{g}/\text{l}$ did produce an embryo response. These values are roughly equivalent to the sperm bioassay EC50's of 143 and < 66 $\mu\text{g}/\text{l}$ endosulfan for 60- and 90-min sperm exposures. The short-duration sperm bioassay is of approximately the same sensitivity to endosulfan as the 96-h embryo bioassays.

Figure 21. Percent composition of the stages of development of sea urchin embryos after 96-h exposures to 0 - 264.9 (initial) µg/l endosulfan in natural seawater. Endosulfan concentrations at the end of 96-h are also indicated (i.e. initial/final).

SECTION VII

SAND DOLLAR BIOASSAYS

SPERM BIOASSAYS

Physical Parameters

Spawning--

Initiation of spawning activity of sand dollars was monitored during the spring of 1979. Approximately half of the sand dollars injected with 0.5 ml of 0.5 M KCl spawned slightly from April 4 to June 29, 1979 (Table 9). Spawning was substantially improved on July 5 (6/8 spawned) with males producing satisfactory quantities of sperm. Egg quantity and maturity was assessed from July 5 - July 27, 1979. Females showed a gradual increase from minimal egg production on July 5 and 12 to an average of 553,880 eggs per female on July 27 (Table 10). Maturity of the eggs was evaluated by adding an excess of sperm for fertilization and scoring the presence or absence of the fertilization membrane in a subsample of 100 eggs. Fertilization success gradually increased from an average of 66.6 percent on July 5 to 98.6 percent on July 27 (Table 10).

Termination of spawning was observed during the fall of 1978 and 1979. The fall 1978 spawn-out occurred approximately the last week of September, as the sand dollars were difficult to spawn with KCl on September 26, 1978. This date closely corresponded to the time when ambient water temperatures began the winter decline (Figure 7). The spawn-out pattern was similar for fall 1979 with 8/10 of the animals spawning on September 26; 4/10 spawning on October 6 and only 1/10 spawning on October 16, 1979.

Sand dollars were not held in thermally conditioned seawater toward the end of their spawning cycle. However, successful extension of the sea urchin spawning cycle suggests that sand dollars can also be held in a ripe condition past normal spawn-out time by holding at a constant temperature of approximately 13-15°C.

Sperm and Egg Quantification--

The density of sperm and eggs in the initial spawning beakers were microscopically assessed by one or two counts before diluting to a standard density (see Appendix Table 1). To assess the accuracy of these counts for determining the dilution factor, 8 samples of sperm and 10 samples of eggs were subjected to 10 replicate counts and the means, 95 percent confidence limits and ranges were recorded (Table 11). The 95 percent confidence limits indicate that the population means should fall within ± 21.5 and

± 15.0 percent of the sample means for sperm and egg counts, respectively. However, as pointed out in Section IV for the sea urchins, the variation between the individual counts is important since the dilution factor was normally determined by only one of two counts per sample. The range values (Table 11) show deviations from the means by as much as 44.8 percent for sperm counts and 46.3 percent for egg counts. Using a target sperm/egg ratio of 5,000,000/5,000 (1,000/1) for each bioassay container, the worst case counting-dilution error could produce sperm/egg ratios as low as 2,760,000/7,315 (= 377/1) or as high as 7,240,000/2,685 (= 2,696/1) for single subsample counts. Based on the sperm/egg ratio tests (see below) for sand dollars, both of these sperm/egg ratios should produce > 90 percent control fertilization. However, the overall sensitivity of the sperm bioassay is partially dependent on the sperm/egg ratio used in the test. Thus, reduction of the counting-dilution error would help to refine the precision of the test.

Effect of Sperm/Egg Ratio--

Three replicated tests were conducted during the 1978 spawning season to determine the minimum sperm/egg ratio required for successful fertilization in control seawater. Average fertilization was > 90 percent at sperm/egg ratios of 500/1 and above for 15-min "exposures" to natural seawater. Ratios ≤ 100/1 produced < 90 percent fertilization (Figure 22). Additional sperm/egg ratio tests were conducted for 30-, 60-, 90- and 120-min sperm "exposure" times during the 1979 spawning cycle. Results of four tests at each "exposure" time generally indicated successful fertilization at sperm/egg ratios ≥ 250/1. Average fertilization success began to decline below 90 percent at sperm/egg ratios ≤ 125/1 (Figure 24). Hence, the usual dosing level of 1000 sperm to 1 egg should normally provide adequate sperm for good control fertilization for sperm "exposure" times up to 120 minutes if the counting-dilution errors are minimized.

All subsequent sperm bioassays with silver and endosulfan were conducted at a sperm/egg ratio of 1000/1 so that the results could be related to the sea urchin bioassays described in Section VI.

Sperm and Egg Viability Through Time--

A preliminary set of six tests investigated the length of time which sand dollar sperm remained viable. Average fertilization of five out of six of the tests showed > 95 percent fertilization for at least 390 minutes and a decrease to 18 percent in 24 hours (Figure 23). One test out of the six showed a marked reduction in sperm viability after only 60 minutes with a decline to 0 percent fertilization in 240 minutes. Thus, monitoring of the control fertilization during tests is important to ensure that an occasional "weak" batch of sperm is weeded out. Figure 23 also shows an increase in fertilization success between 30 and 60 minutes. This effect was also seen for sea urchins (Figure 9) and may indicate that sperm are not fully activated for 1-2 hours after dilution with seawater.

Temperature, Salinity and pH--

To assess the interactive relationships between salinity, temperature, pH and sand dollar fertilization success, a matrix of tests at six salinities, five temperatures and four pH values was conducted using tap water dechlorin-

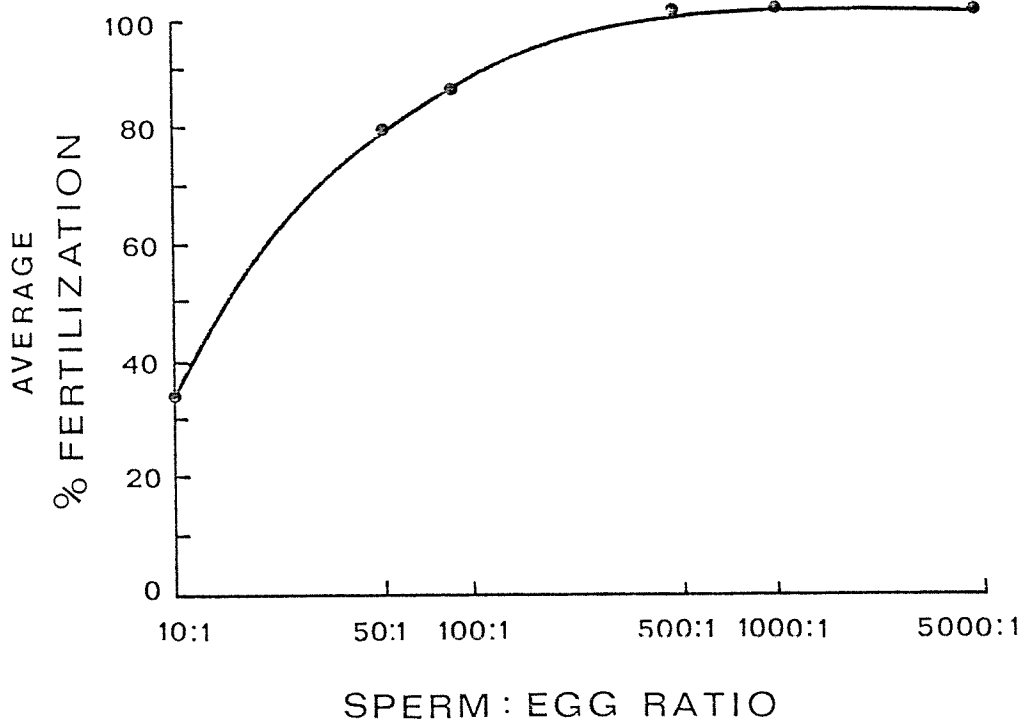

Figure 22. Average percent fertilization after 15-min sand dollar sperm "exposures" to natural seawater at sperm/egg ratios of 10-5000/1.

Figure 23. Long-term viability of sand dollar sperm held at concentrations of 50×10^6 /ml of natural seawater as indicated by average fertilization success over a 24-h time period.

Figure 24. Average percent fertilization after 30-, 60-, 90- and 120-min sperm "exposures" to natural seawater at sperm/egg ratios of 15.6 - 8000/1.

ated with an activated carbon cartridge as the dilution water for salinity reduction. Response surface plots of these tests (Figure 25) indicate that fertilization success was generally best at pH 8.0, 28 ppt salinity and temperatures of 7-17°C. Fertilization was generally poor at all salinities < 28 ppt, especially at pH values < 8.0.

Subsequent matrix tests with silver and endosulfan suggested that the fertilization success of the tests described above was less than should have been expected. The dilution water in the toxicant tests was deionized water from the Fisheries Water Quality Laboratory instead of West Point dechlorinated tap water. We hypothesized that the tap water produced a toxic response not related to the simple osmotic stress of the lowered salinity. To test this hypothesis, the interactive test matrix of salinity, pH and temperature was repeated using deionized water. The results of this second set of tests showed marked increases in fertilization success throughout the entire set of tests (Figure 26). This set of tests showed generally successful fertilization at salinities of 24, 26 and 28 ppt, at the median temperatures of 7, 12 and 17°C, and at pH values of 7.0, 7.5 and 8.0. Temperatures of 2, 22 and 27°C; salinities < 24 ppt and a pH of 8.5 appear to be relatively stressful conditions for sperm functioning.

These two sets of tests emphasize the sensitivity of sperm cells to poor water quality and underscore the need for quality control in all sperm bioassays. Dilution water must be of high quality and bioassay test tubes and spawning containers must be carefully chosen and cleaned. The spawning containers and other laboratory test supplies that may come into contact with the eggs or sperm must be considered as possible sources of toxicity. Glass is generally acceptable, while some plastics have proven to be toxic to the sensitive stages of marine organisms (Bernhard and Zattera, 1970). Certain detergents have also been shown by Bernhard and Zattera to interfere with successful cultivation of marine organisms.

Dissolved Oxygen--

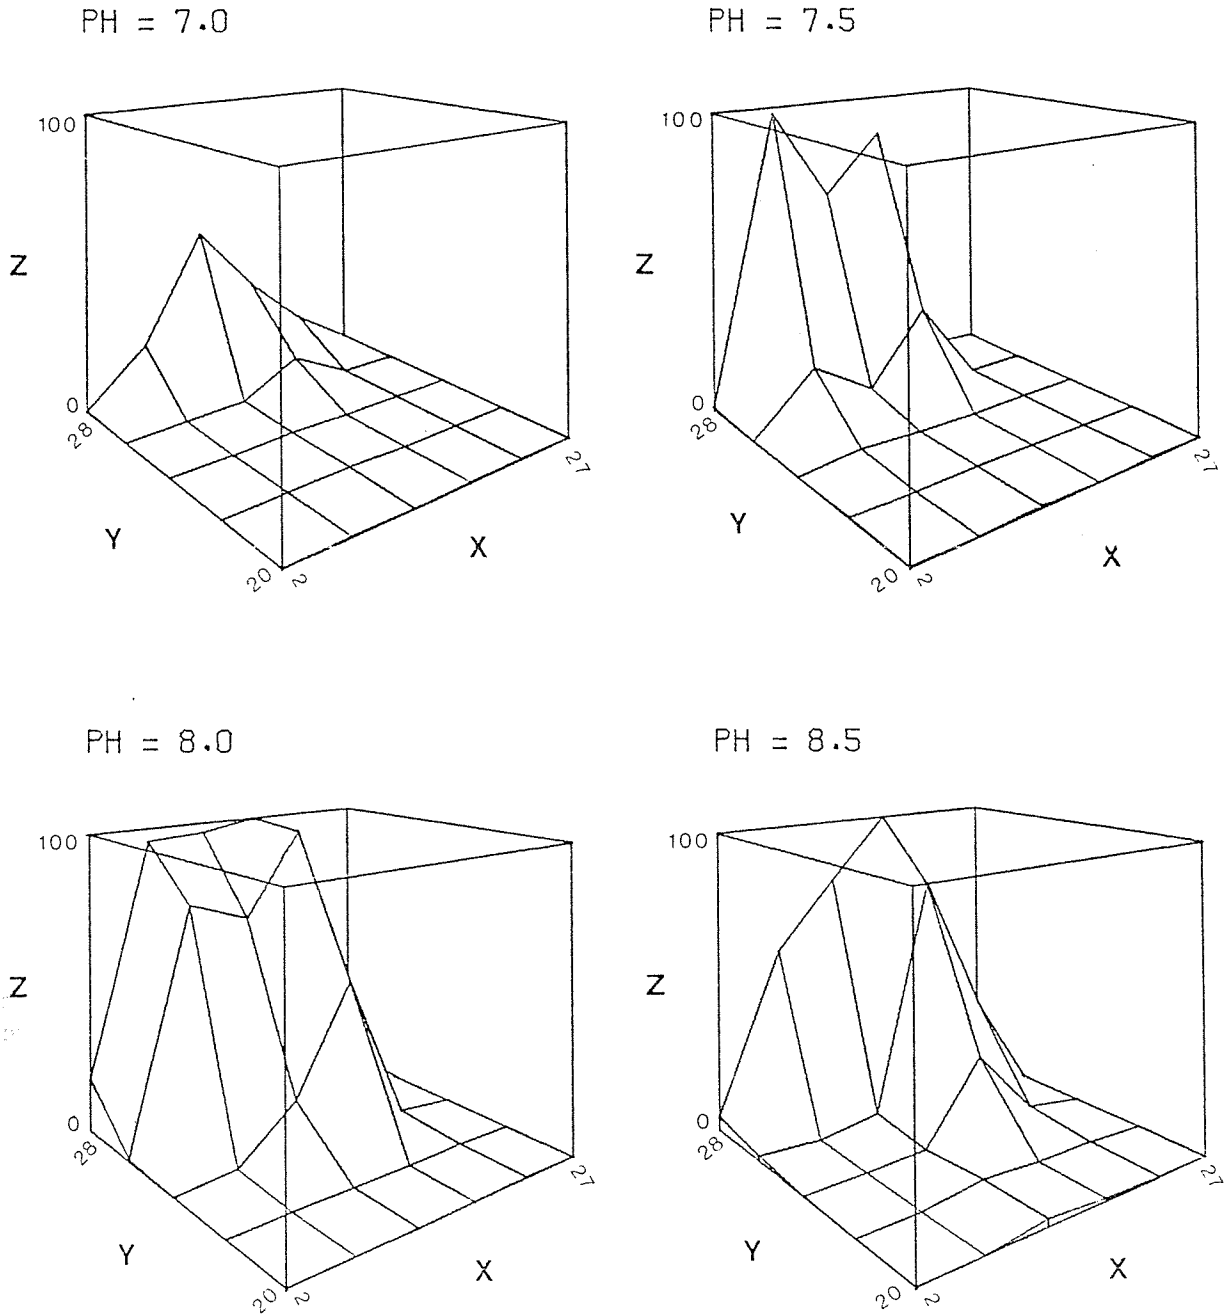

Bioassays of dissolved oxygen content (reduced with nitrogen gas) showed that sperm remained viable during 15-min exposures to levels of dissolved oxygen as low as 0.8 mg/l (Figure 13). The use of sperm bioassay in waters low in dissolved oxygen should pose no problem.

Silver

Time-Concentration Responses--

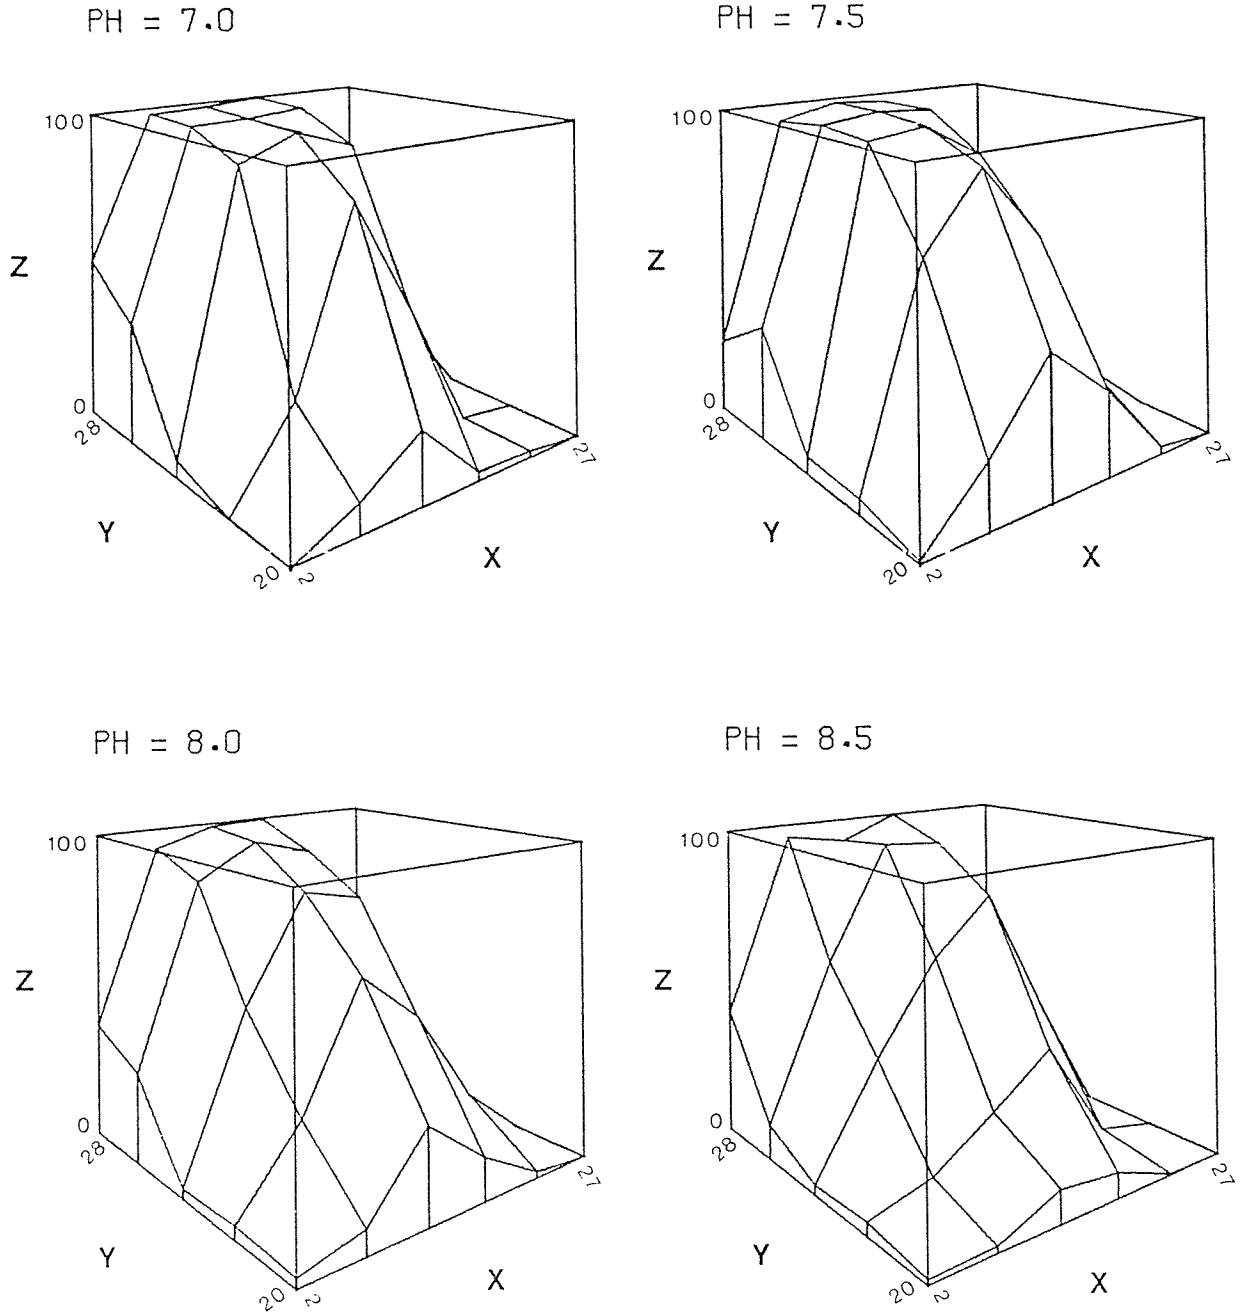

Sand dollar sperm bioassays of silver in natural seawater were conducted with nine silver concentrations and sperm exposure times of 15, 30, 60 and 90 minutes. Each test was replicated four times. The average EC50's and 95 percent confidence limits for 15-, 30-, 60- and 90-min exposure times were 201 ± 105 , 124 ± 27 , 47 ± 11 and 25 ± 12 µg/l silver, respectively.

One interesting characteristic of silver bioassays is that there typically is an increase in fertilization above 0.8 mg/l, especially in the 0.8-1.2 mg/l range (Figure 27). The reasons for this are not entirely understood, however, the 0.8-1.2 mg/l range of silver in seawater represents the concentrations which are at the limits of solubility (at 12°C). Super-

imposed on Figure 27 are lines showing the expected recovery of silver by AAS for filtered and unfiltered samples of silver in seawater. These lines suggest that the dramatic increase in fertilization may be due to a change in form (i.e. decrease in ionic silver) or the physical availability of silver related to the saturation point of silver in seawater. Additional work will be required to substantiate this hypothesis.

Sperm Versus Egg Sensitivity--

Sand dollar eggs exposed to silver in seawater (average EC50 > 250 µg/l) proved to be much less sensitive than sperm exposed to the same silver concentrations (average EC50 = 48 µg/l) for 60 minutes (Figure 28). The sensitivity of both sperm and eggs exposed simultaneously for 60 minutes (exposed in separate tubes and then added together at 60 minutes) was essentially the same as sperm exposed alone (EC50 = 54 µg/l). These results indicate the action of silver is primarily on the sperm cell and that exposure of the eggs does not produce an additive toxic response.

Effect of pH--

Sand dollar sperm bioassays of silver were conducted in natural seawater adjusted to pH 7.5, 8.0 or 8.5 with HCl or NaOH. The EC50's and 95 percent confidence limits for tests at pH 7.5, 8.0 and 8.5 were 53 ± 8 , 50 ± 7 and 41 ± 4 µg/l silver, respectively. The EC50's are essentially the same for pH values of 7.5 and 8.0 indicating no significant difference in silver toxicity. A slight reduction of the EC50 at pH 8.5 was observed. However, response surface plots of sperm bioassays of natural seawater at various pH values, temperatures and salinities (Figures 25 and 26) indicate slightly reduced fertilization as pH increases from 8.0 to 8.5. The slight increase of toxicity of the silver bioassay at pH 8.5 may be due to the increased pH rather than an increase in the toxic effects of silver.

Effects of Temperature and Salinity--

A matrix of bioassays was conducted using a range of silver concentrations in natural seawater at 7, 12 and 17°C; 24, 26 and 28 ppt salinity and pH 8.0. Response surface plotting of the results (Figure 29) shows generally increasing toxicity with increasing silver concentration and decreasing salinity. Toxicity was also greatest at the highest temperature (17°C). The average EC50's (Table 12) for each set of tests within the matrix design support the patterns of toxicity observed above for the response surface plots. It is evident that stresses due to reduced salinity and high temperatures can alter the sensitivity of the sperm bioassay to toxicants such as silver.

Artificial Seawater--

Thirty- and 60-min sperm bioassays of silver in artificial seawater suggested that silver may be more toxic in this matrix than in natural seawater. The average EC50's and 95 percent confidence limits for the 30- and 60-min tests were 56 ± 6 and 25 ± 20 µg/l silver, respectively. These values are substantially less than equivalent 30- and 60-min EC50's for silver bioassays in natural seawater (124 and 47 µg/l silver, respectively).

Endosulfan

Time-Concentration Responses

Sperm bioassays of endosulfan in natural seawater were conducted with nine endosulfan concentrations and sperm exposure times of 30, 60, 90 and 120 minutes. Each test was replicated four times. The average EC50's and 95 percent confidence limits for 30-, 60-, 90- and 120-min exposure times were 157 ± 42 , 151 ± 11 , 113 ± 27 and 80 ± 18 $\mu\text{g}/\text{l}$ endosulfan, respectively. Sperm sensitivity to endosulfan increased with increased exposure time.

Sperm Versus Egg Sensitivity--

Endosulfan bioassays using 60-min exposures of sperm only, eggs only and sperm plus eggs (simultaneous exposure in separate containers) were conducted to assess the relative sensitivity between eggs and sperm. The eggs generally proved to be more resistant to endosulfan toxicity than sperm (egg and sperm average EC50's = 356 ± 57 and 286 ± 82 $\mu\text{g}/\text{l}$, respectively) (Figure 30). Sperm and eggs exposed simultaneously were generally more sensitive to endosulfan than either exposed singly (sperm plus egg average EC50 = 224 ± 470 $\mu\text{g}/\text{l}$). The toxic effects of endosulfan may be at least partially additive when both sets of gametes are exposed simultaneously.

Effects of pH--

Sand dollar sperm bioassays of endosulfan were conducted with natural seawater adjusted to pH 7.5, 8.0 and 8.5 with HCl or NaOH. The toxicity of endosulfan was essentially the same in all three tests. Average EC50's and 95 percent confidence limits for tests at pH 7.5, 8.0 and 8.5 were 231 ± 33 , 271 ± 20 and 229 ± 39 $\mu\text{g}/\text{l}$ endosulfan, respectively.

Effects of Temperature and Salinity--

A matrix of sand dollar sperm bioassays was conducted using a range of endosulfan concentrations in natural seawater at 7, 12 and 17°C; 24, 26 and 28 ppt salinity and pH 8.0. Response surface plots of the results show generally decreasing fertilization success with increasing endosulfan (Figure 31). Fertilization success is also generally less at salinities < 28 ppt and at 7°C. The higher toxic response at 7°C is in contrast to the silver matrix tests (Figure 29) where a greater toxic response occurred at 17°C instead of at 7°C. The responses graphed in Figure 31 are reinforced by the average EC50's calculated for each set of tests at a specific temperature and salinity (Table 13).

Artificial Seawater--

Endosulfan in artificial seawater did not prove to be more toxic to sand dollar sperm than endosulfan in natural seawater. Thirty- and 60-min EC50's for endosulfan in artificial seawater were 193 ± 62 and 184 ± 47 $\mu\text{g}/\text{l}$ versus 157 ± 42 and 151 ± 11 $\mu\text{g}/\text{l}$ for natural seawater. These results are different than those using sea urchin sperm where endosulfan was substantially more toxic in artificial seawater. Additional tests will be required to establish a relationship between chemical toxicity and type of seawater.

Chemical Form of Endosulfan--

Sand dollar sperm bioassays of four chemical forms of endosulfan (α , β ,

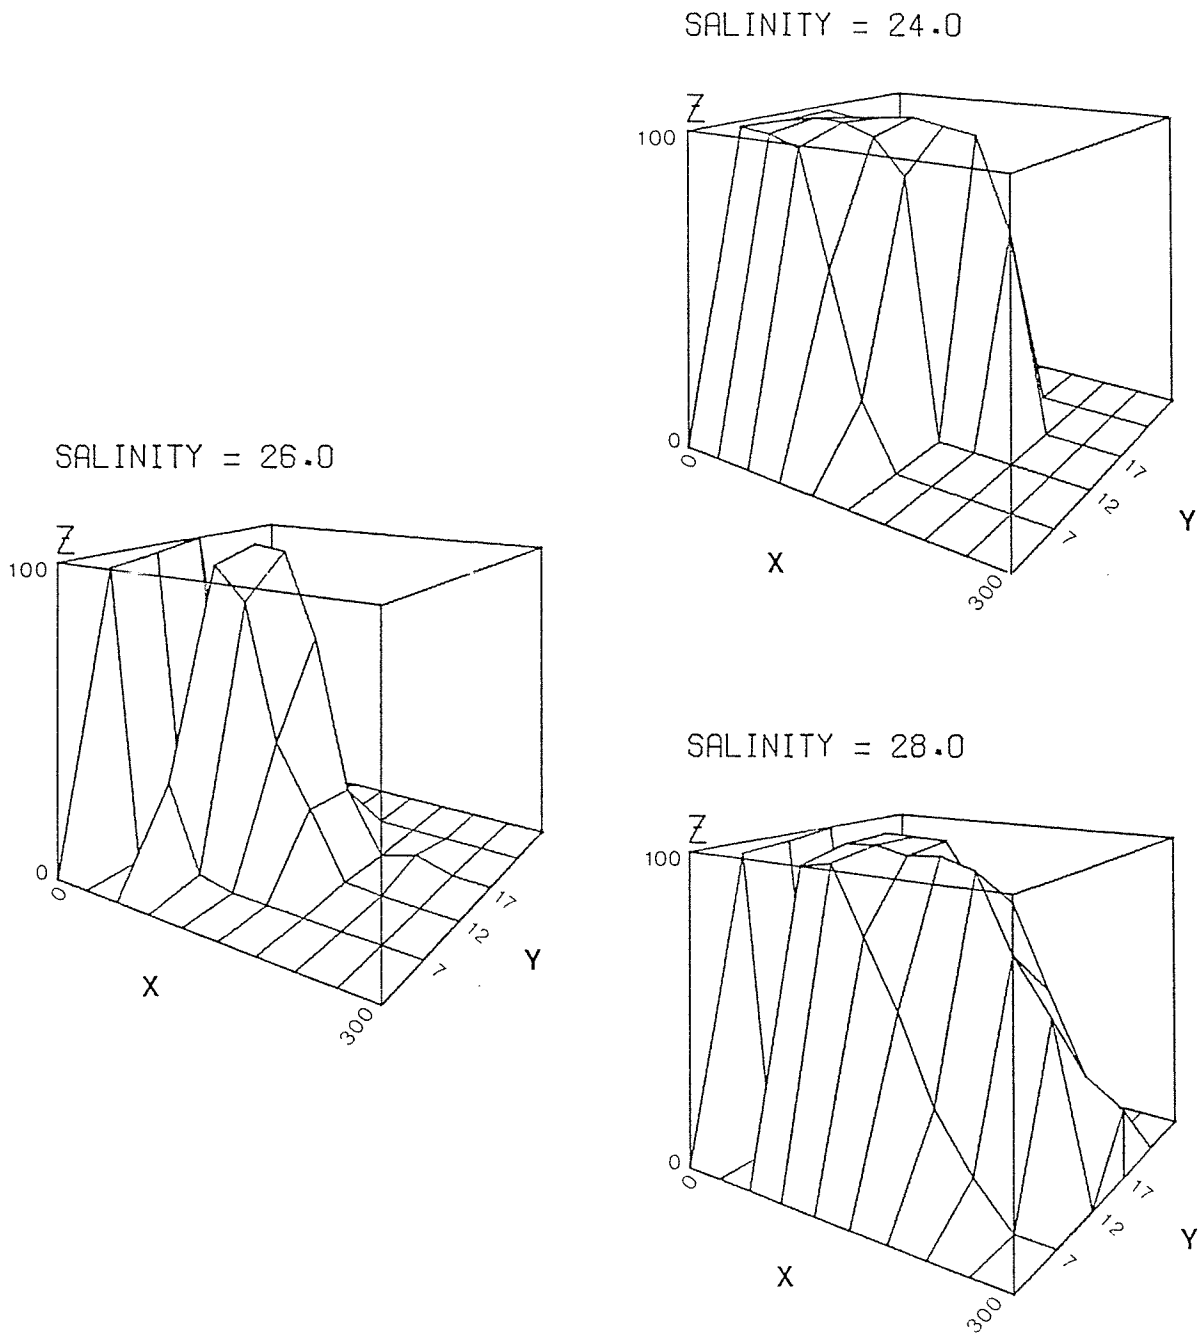

Figure 30. Average fertilization success following 60-min sand dollar sperm, egg, or sperm and egg exposures to endosulfan in natural seawater.

sulfate and ether) were conducted to assess the relative toxicity between these forms in natural seawater. The resulting 60-min EC50's and 95 percent confidence limits of endosulfan α , β , sulfate and ether were 262 ± 43 , $> 48 < 74$, 208 ± 64 and 533 ± 622 $\mu\text{g}/\text{l}$, respectively. The relative toxicity of these four forms as determined by sperm bioassay was $\beta > \text{sulfate} > \alpha > \text{ether}$.

Interactive Toxicity of Silver and Endosulfan--

To test for possible synergistic, antagonistic or additive toxicity of combinations of silver and endosulfan, a matrix design of silver and/or endosulfan concentrations in natural seawater was tested with 30-min exposures of sand dollar sperm. Silver was added in calculated concentrations of 0, 25, 50, 75, 100 and 125 $\mu\text{g}/\text{l}$. Endosulfan was tested at measured concentrations of 0, 58, 105, 147 and 194 $\mu\text{g}/\text{l}$ (Table 14).

The resulting pattern of egg fertilization showed increasing toxicity of silver (≥ 25 $\mu\text{g}/\text{l}$) and endosulfan (≥ 147 $\mu\text{g}/\text{l}$) alone as well as generally additive toxicity of combinations of these two toxicants (Table 15).

Summary of Sand Dollar Sperm Bioassay Data--

Individual and mean EC50's, fiducial limits, confidence limits and test conditions of silver and endosulfan bioassays are summarized in Appendix Tables 4 and 5.

EMBRYO BIOASSAYS

Silver

A 72-h bioassay of sand dollar embryos was conducted to determine the relative toxicity of silver to sperm and developing embryos. The results show no evident effect of silver on development at calculated concentrations of 3.12, 6.25 and 12.5 $\mu\text{g}/\text{l}$ (Table 16). Slight retardation of development was observed in 25 $\mu\text{g}/\text{l}$ with progressively more retardation from 50 to 1000 $\mu\text{g}/\text{l}$. Embryos in 200 $\mu\text{g}/\text{l}$ suffered high mortality and cytolysis while embryos in 400 and 1000 $\mu\text{g}/\text{l}$ showed less mortality and cytolysis. The 200 $\mu\text{g}/\text{l}$ embryos were at the post-hatch stage while embryos in 400 and 1000 $\mu\text{g}/\text{l}$ silver were retarded to the pre-hatch stage. The fertilization membrane evidently afforded an extra margin of protection to the pre-hatch embryos.

The results of the 72-h embryo bioassays of silver closely correspond to the toxicity of silver determined by sperm bioassays (15-, 30- 60- and 90-min sperm EC50's = 201, 124, 47 and 25 $\mu\text{g}/\text{l}$ silver, respectively). The lowest levels of toxicity determined by the 72-h embryo bioassay were successfully predicted by 60- to 90-minute sperm bioassays with less subjectivity and time.

Endosulfan

A 72-h bioassay of sand dollar embryos was conducted to determine the relative toxicity of endosulfan to sperm and developing embryos. The results show no effect of endosulfan on development at initial measured concentrations of 48.2, 81.9 and 98.0 $\mu\text{g}/\text{l}$. Slight retardation of embryo

development was observed in 157.6, 187.8, 226.9 and 256.6 $\mu\text{g}/\text{l}$ endosulfan and more pronounced retardation from 326.1 - 423.2 $\mu\text{g}/\text{l}$ (Table 17). Additionally, many of the embryos were poorly formed in endosulfan concentrations $\geq 187.8 \mu\text{g}/\text{l}$. Survival was essentially the same in controls (0 $\mu\text{g}/\text{l}$) and all endosulfan concentrations.

There was an average decrease of endosulfan in the test containers of 47.1 percent during the 72-h exposure period. Thus, the concentrations of endosulfan affecting development as noted above are conservative estimates of toxicity.

Sand dollar sperm bioassays appear to be more sensitive indicators of endosulfan toxicity than 72-h embryo bioassays (30-, 60-, 90- and 120-min sperm EC50's = 157, 151, 113 and 80 $\mu\text{g}/\text{l}$ endosulfan, respectively. The lowest level of toxicity detected by embryo bioassay was 157.6 $\mu\text{g}/\text{l}$, which is essentially the same as the 30-min EC50 for the sperm bioassay. Sperm exposure times > 30 minutes further increased the sensitivity of the sperm bioassay to endosulfan.

SECTION VIII

DISCUSSION

The sperm bioassay is proving to be a very quick and sensitive test for many toxicants in marine waters. Sea urchin sperm sensitivity to silver and endosulfan generally agree with the levels of toxicity reported for other aquatic animals with these substances (see Section III C). Exceptions to this may be the greater sensitivity of fish, especially in long-term tests, and some invertebrate larval stages.

The sperm bioassay has most of the advantages of both static and flow-through bioassays with few of the disadvantages. Being a static test, it utilizes single batches of dilution water with constant, closely defined water quality characteristics. Temperature fluctuations are avoided by using a constant-temperature water bath. The short duration of the sperm assay minimizes loss or degradation of the toxicant in the test containers and facilitates toxicant analysis. The test response (percent eggs fertilized) is easily quantified in an objective manner and the results easily analyzed by accepted standard bioassay statistical methodology. Adult animals are easily obtained in coastal marine waters and maintained in the laboratory. The adult animals are rarely harmed by the KCl spawning treatment allowing them to be used repeatedly (2 to 3 times with about 30-day resting intervals) as sources of gametes or returned unharmed to their natural environment.

This test should prove to be especially useful for monitoring the variable toxicity of chemicals which change form or degrade rapidly through time after introduction into seawater, or complex wastewater samples which normally receive extensive chemical characterization but no biological assessment. The sperm bioassay should also prove to be a valuable biomonitoring procedure for receiving water quality as well as a standardized laboratory procedure. Its use in a matrix arrangement with multiple bioassay parameters has been illustrated in this report. The synergistic or antagonistic interactions of combinations of toxicants can also be analyzed in a similar matrix design.

The sperm bioassay described in this report needs further refinements to optimize its usefulness and repeatability. The tests reported here used a ratio of 1000 sperm/egg for both species. However, the results suggest that a 1000 sperm/egg ratio may not be high enough for green sea urchin sperm while 250 sperm/egg may be a satisfactory ratio for sand dollars. Optimum sperm/egg ratios should be determined for each species. The optimum ratio is that which yields consistent control fertilization of ≥ 90 percent

but which is not so high as to decrease the sensitivity of the test to toxicants.

Between-test variability should be reduced to narrow the confidence limits of the mean EC50's and facilitate comparisons between treatments or species. Variability can be reduced by more accurate enumeration of initial sperm and egg densities so that the final dilutions to pre-determined standard densities will yield minimal variability between individual sperm and egg samples. Fiducial and confidence limits around an EC50 may be tightened by increasing the number of test replicates per treatment; the optimum number probably being a compromise between the number required for a solid statistical base on the one hand and those realistically possible based on time and funds on the other.

Disposable test tubes (with caps) should help to refine the sperm bioassay by reducing the time and effort involved in washing test tubes and storage vials. The eggs would be preserved by adding formalin to each test tube after the egg fertilization period and subsequently capping each tube until the eggs could be counted. This procedure would also eliminate any possibility of contamination from previous toxicant bioassays or from cleaning agents.

We hypothesize that sperm from many species of sea urchins (and sand dollars) are of essentially equal sensitivity to toxic substances. This report has provided an overview of the development and use of a sperm bioassay for testing toxic substances. The sensitivity of sperm from two echinoderm species was compared using two reference toxicants. We found that green sea urchin sperm and sand dollar sperm are roughly of equal sensitivity to both silver and endosulfan based on generally overlapping 95 percent confidence intervals of the mean EC50's of both species for the time-concentration tests (Figures 32 and 33). These comparisons are admittedly rough (and non-statistical), as the test methods were continually undergoing refinement and the optimum sperm/egg ratio may be different for each species. Additional replicates (*i.e.* > 4) may be necessary to yield reasonably tight estimates of a mean EC50. Even then, valid statistical comparisons between species and/or treatments may not be completely possible. Mean EC50's and 95 percent confidence limits based on the variation within a population of individual replicate EC50's do not take into consideration the variation (*i.e.* fiducial limits) around each individual EC50. Thus, methods of comparisons of EC50's must be refined along with the testing methodology.

Improved availability of ripe test animals is desirable. Presently, by maintaining green sea urchins in cooled seawater during their normal spawn-out period, gametes can be obtained from approximately February to June. Sand dollars appear to be normally ripe from June to October and possibly through November if thermally conditioned. December and January may represent periods of time when gametes may not be available from these two species. Testing should be extended to other species of sea urchins to close this gap. The purple sea urchin, Strongylocentrotus purpuratus, has been widely used for experimental biology purposes along the U.S. Pacific Coast. This species is plentiful on the open coast and has a prolonged

Figure 32. Comparison of sea urchin and sand dollar EC50's and 95% confidence intervals for 15-, 30-, 60- and 90-min sperm exposures to silver.

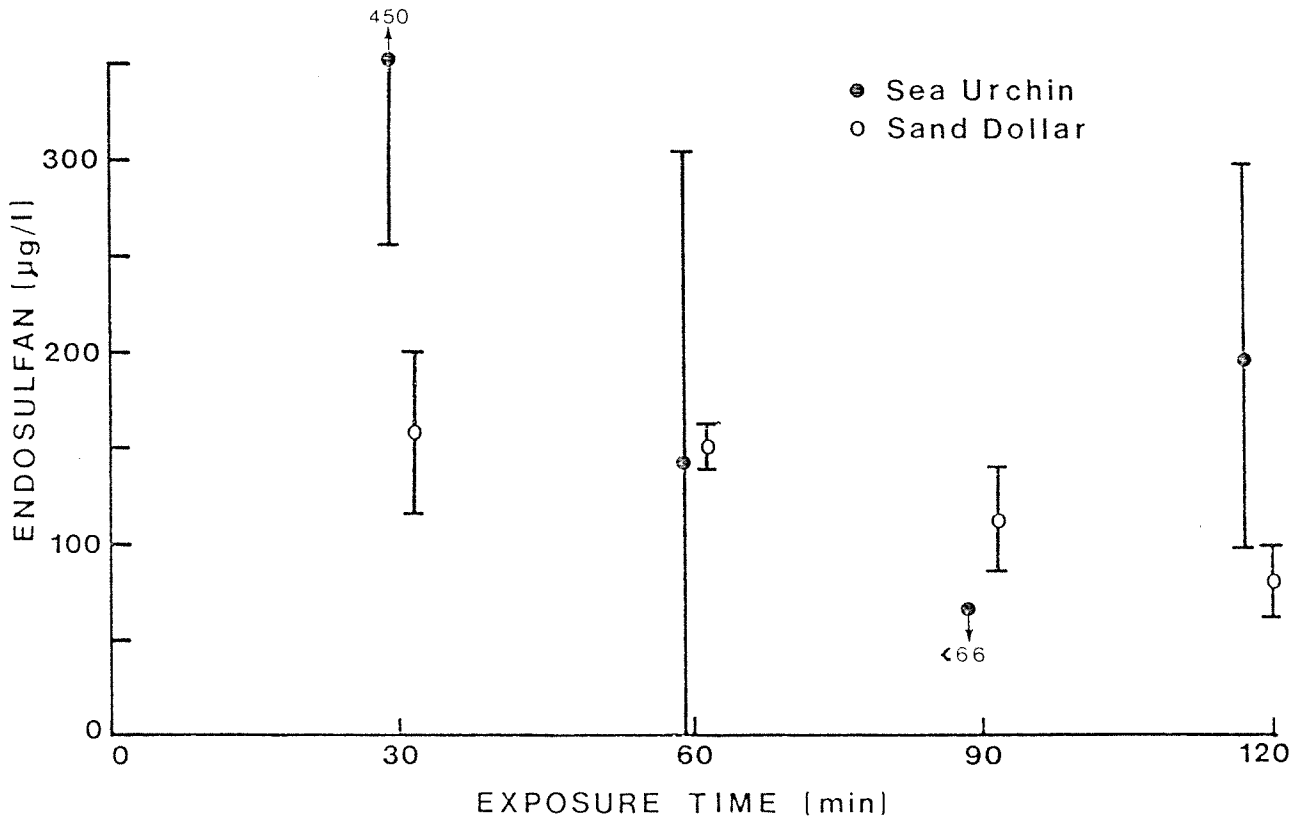

Figure 33. Comparison of sea urchin and sand dollar EC50's and 95% confidence intervals for 30-, 60-, 90- and 120-min sperm exposures to endosulfan.

spawning cycle compared to S. droebachiensis (Himmelman 1978) with active spawning beginning in December (Cochran and Engelman 1975). The red urchin, S. franciscanus, is also abundant on the Pacific Coast. Should sperm of these species all prove equally sensitive to various toxicants, it would then be interesting to compare our results with similar testing of other U.S. and foreign species.

An extended corollary of this hypothesis is that sperm cells from many other marine animals exhibiting external fertilization may show the same sensitivity in this test procedure as sea urchin sperm. Oysters (Crassostrea gigas) should provide a valuable comparison since they can be thermally conditioned to spawn out of season and the embryos serve as the basis of the Washington State receiving water quality bioassay (Woelke 1972).

The use and application of the sperm bioassay can be further extended by conducting comparative 96-h bioassays with selected species of marine fish and invertebrates. Such comparisons will relate the sensitivity of the sperm bioassay to existing toxicity data and help validate this test for use in refining water quality criteria and for assessing potential ecological impacts.

SECTION X

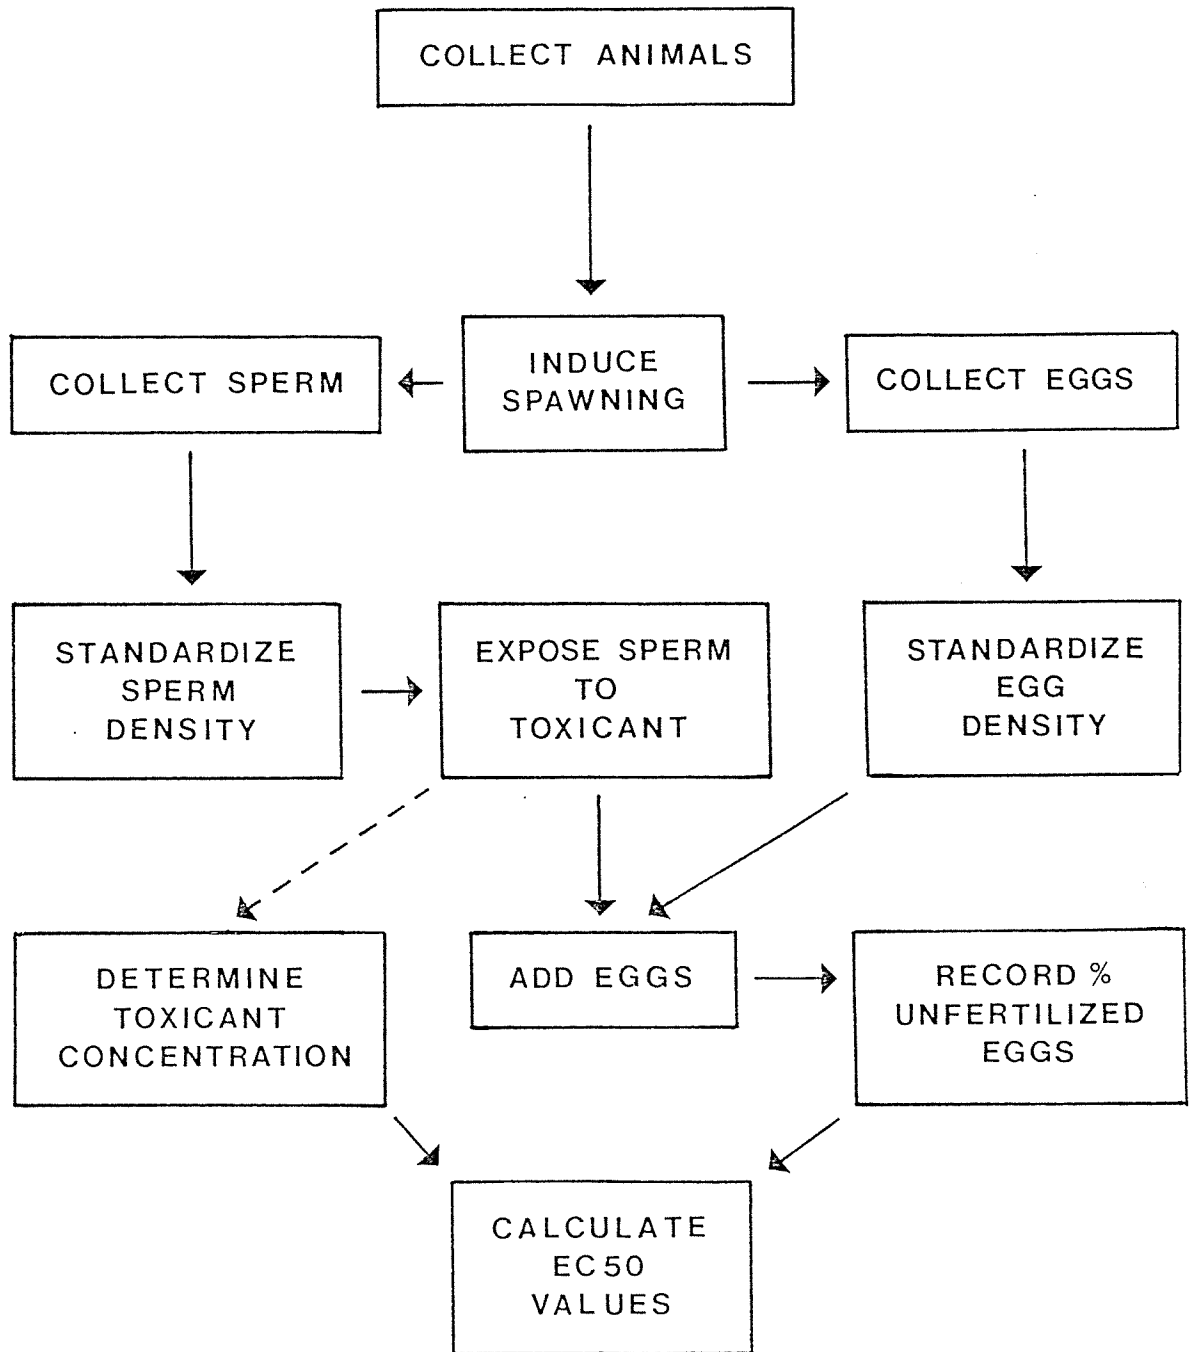

APPENDIX

APPENDIX TABLE 1. PRELIMINARY ECHINODERM SPERM BIOASSAY PROTOCOL.

| STEP | PROCEDURE |
|------|--|
| 1 | Collect test animals from sites not subject to compromise by municipal or industrial discharges. Hold animals in the laboratory in flowing seawater filtered through gravel and sand filters and activated carbon. Feeding is unnecessary for animals not held for extended periods of time. |
| 2 | Spawn animals by inverting over a 100-ml beaker full of seawater. Inject approximately 0.5 ml (for sand dollars) or 1.0 ml (for sea urchins) of 0.5 M potassium chloride (KCl) into celomic cavity through the peristomal membrane or oral opening (Tyler 1949). Allow to spawn 10-20 minutes. |
| 3 | Decant some seawater from the 100-ml beakers containing sperm and mix thoroughly. Decant eggs (from several females, if necessary) into a larger beaker and wash with fresh seawater two to three times. Let settle between washes. |
| 4 | Determine sperm density in concentrated samples by adding 0.1-1.0 ml subsample to 10 ml glacial acetic acid (to kill sperm) and seawater adjusted to 100 ml final volume. Add 1 drop of diluted sperm solution to a hemacytometer counting chamber. Let sperm settle 15-20 minutes. Count sperm as per standard method for red blood cell counts. Determine sperm density in the concentrated solution by the following formula: |
| | $\# \text{ Sperm/ml} = \frac{(\text{Dilution factor})(\# \text{ of sperm counted})(4,000)}{\text{Number of squares counted}} (1,000)$ |
| 5 | Standardize sperm density to $50 \times 10^6/\text{ml}$ by the following formula: |
| | $\text{Dilution factor} = \frac{\text{Number of sperm in concentrated solution}}{50 \times 10^6}$ |
| 6 | Determine egg density by a subsample (0.1-1.0 ml) counted directly under a dissecting microscope at 10-20X. |

APPENDIX TABLE 1. (continued)

| STEP | PROCEDURE |
|------|---|
| 7 | Standardize egg density to 5×10^3 /ml by the following formula: Dilution factor = $\frac{\text{Number of eggs in concentrated solution}}{5 \times 10^3}$ |
| 8 | Add 0.1 ml standardized sperm solution to each test tube containing 25.0 ml total volume of toxicant/seawater or seawater (control). Mix gently and allow to incubate for desired sperm exposure time (usually 15-60 minutes). |
| 9 | Add 1.0 ml standardized egg solution to each test tube following the desired sperm exposure period. Mix gently and allow 20 minutes for eggs to fertilize and settle. |
| 10 | Decant most solution from test tubes and pour the settled eggs into vials containing 10-15% formalin in seawater. Cap vials and store until analyzed. |
| 11 | To analyze, mix samples and pour a subsample onto a microscope slide etched with a counting grid. Determine percent unfertilized eggs by scoring presence or absence of the fertilization membrane of 100 eggs. Eggs with only partial membrane formation are counted as unfertilized. Damaged eggs are not counted. |
| 12 | Repeat tests that exhibit less than 90% control fertilization. Adjust test responses for natural responsiveness of controls (when $\geq 90\%$ and $< 100\%$) by Abbott's formula (Finney 1971): Adjusted test response = $\frac{\% \text{ Test response} - \% \text{ Control response}}{100 - \% \text{ Control response}} (100)$ |
| 13 | Determine test EC50's and 95% fiducial limits by probit analysis (Finney 1971), using adjusted test responses and toxicant concentration data from split sample chemical analyses or from calculated concentrations. |

Appendix Figure 1. Simplified flow diagram of the echinoderm sperm bioassay procedures.
